ABSTRACT

Knowing whether a carbon surface is positively or negatively charged (and to what extend) depending on the characteristics of the medium in which is dispersed could be useful for certain applications of the carbon. In particular, for the electrochemical applications of carbon materials, like electrodes for EDL capacitors, anodes for batteries, etc. This is, however, a non straightforward issue since the charges developed in a carbon surface depends both on its, generally complex, surface chemistry and, on the characteristics of the medium in which is embedded (i.e. pH). In this work some assumptions are made in order to simplify de problem and to come out with an approximate solution.

Key words: Carbon, Surface Chemistry; Charge Distribution; pH; Point of Zero Charge

INTRODUCTION

Carbons are amphoteric by nature, which means that acidic and basic functionalities coexist on their surface. When a carbon is placed in an aqueous medium, these functionalities, depending on the pH and the nature of the functionalities, may give rise to positive or negative charges. Table 1 summarizes the main proposed models for oxygen-containing functionalities, which are the most abundant surface groups present on carbons.
Table 1. Main proposed models of oxygen-containing surface groups that can be present on carbon surfaces and their evolution in acidic or basic media.

Knowledge of how a carbon surface is charged is of crucial importance for a number of processes, particularly when carbon materials are used as electrodes.

However, the charge developed by a carbon when it is put into contact with an aqueous solution cannot be accurately predicted given the complexity of the functionalities that typically coexist on its surface.
SIMPLIFIED MODEL AND APPROXIMATE SOLUTION

An approximate solution to this problem is provided by the following simple model (Figure 2):

![Figure 2](image)  

**Figure 2.** Simplified representation of the charge exchange between the carbon surface and the aqueous media.

When the pH of an aqueous medium, and therefore the \([H^+]\), is altered by the addition of \(H^+\) (by adding, for example, an acid) or by the removal of \(H^+\) (by adding, for example, a base) the carbon surface trends to counterbalance the newly created situation by adsorbing \(H^+\) (or alternatively releasing \(OH^-\) or \(e^-\)) or by releasing \(H^+\) (or alternatively adsorbing \(OH^-\) or capturing \(e^-\)) respectively. This response mechanism gives rise to the formation of (new) positive or negative charges respectively on the carbon surface. Note that although equations given in Table 1 are presented as equilibrium, this is merely a model, since carbons are in suspension (not in solution) and so, the classical equilibrium equations cannot be applied here.

Assuming this simplification to be correct, the proportion of positive and negative charges on a carbon surface can be expressed as a function of the point of zero charge (\(pH_{pzc}\)) (i.e., the nature of the carbon surface groups) and the pH (i.e., the nature of the aqueous medium).
The proportion of positive charges on a given surface can be then expressed as:

\[ F_{\%+}(pH) = \frac{n(+) \times 100}{n(+) + n(-)} \]  \hspace{1cm} (1) \]

where \( n(+) \) is the number of positive charges and \( n(-) \) is the number of negative charges.

Assuming that the amount of positive charges is proportional to the concentration of protons in the aqueous medium and the amount of negative charges is inversely proportional to the concentration of protons (in accordance with the simplification made above) then:

\[ n(+) = k_1[H^+] = k_110^{-pH} \]  \hspace{1cm} (2) \]

\[ n(-) = \frac{k_2}{[H^+]} = k_210^{pH} \]  \hspace{1cm} (3) \]

Substituting into equation (1), we obtain:

\[ F_{\%+}(pH) = \frac{k_110^{-pH} \times 100}{k_110^{-pH} + k_210^{pH}} \]  \hspace{1cm} (4) \]

Multiplying by \( 10^{pH} \):

\[ F_{\%+}(pH) = \frac{100k_1}{k_1 + k_210^{2pH}} \]  \hspace{1cm} (5) \]

Dividing by \( k_1 \) and defining \( k \) as \( \frac{k_1}{k_2} \):

\[ F_{\%+}(pH) = \frac{100}{1 + k10^{2pH}} \]  \hspace{1cm} (6) \]

Taking into account the definition of the point of zero charge:
if \( pH = PH_{pzc} \Rightarrow F_{\nu^+}(pH_{pzc}) = 50 \) \hspace{1cm} (7)

given that at the point of zero charge \( (pH_{pzc}) \) the amount of positive charges must be equal to the amount of negative charges, then:

\[
50 = \frac{100}{1 + k10^{-2pH_{pzc}}} \Rightarrow 50 + 50k10^{-2pH_{pzc}} = 50 \cdot 2 \Rightarrow k = 10^{-2pH_{pzc}} \hspace{1cm} (8)
\]

Substituting \( k \) into equation (6):

\[
F_{\nu^+}(pH) = \frac{100}{1 + 10^{-2pH_{pzc}}} \cdot 10^{-2pH} = \frac{100}{1 + 10^{2(pH - pH_{pzc})}} \hspace{1cm} (9)
\]

This function can be represented for different \( pH_{pzc} \) in the following diagrammatic form:

**Figure 2.** Percentage of positive charges on a carbon surface as a function of the pH of the medium. Each curve represents a different carbon, whose \( pH_{pzc} \) is the pH at which the curve intersects the 50% charge line.
CONCLUSIONS

Assuming the above line of reasoning to be valid, then only when $\text{pH} = \text{pHPZC}$, are the carbon surfaces neutral. A slight shift in this situation (ca. 1 unit of pH) would give rise to a carbon surface that is either totally positively or negatively charged. This means that, in practice, carbon surfaces will be negatively charged when the pH of the aqueous medium is slightly above the pH$_{PZC}$ or vice versa.

This model allows the relative proportion of electrical charges to be known, but not their amount. However, it seems reasonable to suppose that the greater the difference between the pH$_{PZC}$ and the pH of the aqueous medium, the greater the amount of electrical charges (either positive or negative, depending on the situation).

In any case, this may serve as a starting point for making more sophisticated calculations in order to ascertain the electrical charge distribution on carbon surfaces.
