ABSTRACT

Aims. Our goal is to estimate empirically the cosmic variance that affects merger fraction studies based on close pairs for the first time.

Methods. We compute the merger fraction from photometric redshift close pairs with $10^{-3} h^{-1} \text{kpc} \leq r_p \leq 50 h^{-1} \text{kpc}$ and $\Delta z \leq 500 \text{ km s}^{-1}$ and measure it in the 48 sub-fields of the ALHAMBRA survey. We study the distribution of the measured merger fractions that follow a log-normal function and estimate the cosmic variance $\sigma_v$ as the intrinsic dispersion of the observed distribution. We develop a maximum likelihood estimator to measure a reliable $\sigma_v$ and avoid the dispersion due to the observational errors (including the Poisson shot noise term).

Results. The cosmic variance $\sigma_v$ of the merger fraction depends mainly on (i) the number density of the populations under study for both the principal ($n_1$) and the companion ($n_2$) galaxy in the close pair and (ii) the probed cosmic volume $V_c$. We do not find a significant dependence on either the search radius used to define close companions, the redshift, or the physical selection (luminosity or stellar mass) of the samples.

Conclusions. We have estimated the cosmic variance that affects the measurement of the merger fraction by close pairs from observations. We provide a parametrisation of the cosmic variance with $n_1$, $n_2$, and $V_c$, $\sigma_v \propto n_1^{0.34}V_c^{0.49}(n_2/n_1)^{0.37}$. Thanks to this prescription, future merger fraction studies based on close pairs could properly account for the cosmic variance on their results.

Key words. galaxies: interactions – galaxies: fundamental parameters – galaxies: statistics

1. Introduction

Our understanding of the formation and evolution of galaxies across cosmic time has been greatly improved in the last decade thanks to deep photometric and spectroscopic surveys. Some examples of these successful deep surveys are SDSS (Sloan Digital Sky Survey, Abazajian et al. 2009), GOODS (Great Observatories Origins Deep Survey, Giavalisco et al. 2004), AEGIS (All-Wavelength Extended Groth Strip International Survey, Davis et al. 2007), ELAIS (European Large-Area ISO Survey, Rowan-Robinson et al. 2004), COSMOS (Cosmological Evolution Survey, Scoville et al. 2007), MGC (Millennium Galaxy Catalogue, Liske et al. 2003), VVDS (Vimos VLT Deep Survey, Le Fèvre et al. 2005, 2013), DEEP (Deep Extragalactic Evolutionary Probe, Newman et al. 2013), zCOSMOS (Lilly et al. 2009), GNS (GOODS NICMOS Survey, Conselice et al. 2011), SXDS (Subaru/XMM-Newton Deep Survey, Furusawa et al. 2008), or CANDELS (Cosmic Assembly

One fundamental uncertainty in any observational measurement derived from galaxy surveys is the cosmic variance \((\sigma_v)\), arising from the underlying large-scale density fluctuations and leading to variances larger than those expected from simple Poisson statistics. The most efficient way to tackle the cosmic variance is to split the survey in several independent areas in the sky. This minimises the sampling problem and is better than increasing the volume in a wide contiguous field (e.g., Driver & Robotham 2010). However, observational constraints (depth vs. area) lead to many existing surveys that have observational uncertainties dominated by the cosmic variance. Thus, a proper estimation of \(\sigma_v\) is needed to fully describe the error budget in deep cosmological surveys.

The impact of the cosmic variance in a given survey and redshift range can be estimated using two basic methods: theoretically, by analysing cosmological simulations (e.g., Somerville et al. 2004; Trenti & Stiavelli 2008; Stringer et al. 2009; Moster et al. 2011), or empirically, by sampling a larger survey (e.g., Driver & Robotham 2010). Unfortunately, previous studies only estimate the cosmic variance affecting number density measurements and do not tackle the impact of \(\sigma_v\) in other important quantities as the merger fraction. Merger fraction studies based on close pair statistics measure the correlation of two galaxy populations at small scales \((\lesssim 100 \, h^{-1} \, \text{kpc})\), so the amplitude of the cosmic variance and its dependence on galaxy properties, probed volume, etc. should be different than those in number density studies. In the present paper, we take advantage of the unique design, depth, and photometric redshift accuracy of the ALHAMBRA\(^1\) (Advanced, Large, Homogeneous Area, Medium-Band Redshift Astronomical) survey (Moles et al. 2008) to estimate empirically, for the first time, the cosmic variance that affects close pair studies. The ALHAMBRA survey has observed eight separate regions of the northern sky, comprising 48 sub-fields of \(\sim 180 \, \text{arcmin}^2\) each that can be assumed as independent for our purposes. Thus, ALHAMBRA provides 48 measurements of the merger fraction across the sky. The intrinsic dispersion in the distribution of these merger fractions, which we characterise in the present paper, is an observational estimation of the cosmic variance \(\sigma_v\).

The paper is organised as follows. In Sect. 2, we present the ALHAMBRA survey and its photometric redshifts, and in Sect. 3, we review the methodology to measure close pair merger fractions when photometric redshifts are used. We present our estimation and characterisation of the cosmic variance for close pair studies in Sect. 4. In Sect. 5, we summarise our work and present our conclusions. Throughout this paper, we use a standard cosmology with \(\Omega_m = 0.3, \Omega_\Lambda = 0.7, H_0 = 100 \, h \, \text{km s}^{-1} \, \text{Mpc}^{-1}\), and \(h = 0.7\). Magnitudes are given in the AB system.

2. The ALHAMBRA survey

The ALHAMBRA survey provides a photometric data set over 20 contiguous, equal-width \((\sim 300 \, \text{Å})\), non-overlapping, medium-band optical filters \((3500 \, \text{Å} - 9700 \, \text{Å})\) plus 3 standard broad-band near-infrared (NIR) filters \((J, H, K_s)\) over 8 different regions of the northern sky (Moles et al. 2008). The survey has the aim of understanding the evolution of galaxies throughout cosmic time by sampling a large enough cosmological fraction of the universe, for which reliable spectral

Fig. 1. Schematic view of the ALHAMBRA field’s geometry in the sky plane. We show the eight sub-fields (one per LAICA chip) of the field ALHAMBRA-6. The black and red squares mark the two LAICA pointings in this particular field. The geometry of the other seven fields is similar. A colour version of this plot is available in the electronic edition.

2.1. Bayesian photometric redshifts in ALHAMBRA

We rely on the ALHAMBRA photometric redshifts to compute the merger fraction (Sect. 3). The photometric redshifts used all
over the present paper are fully presented and tested in Molino et al. (2013), and we summarise their principal characteristics below.

The photometric redshifts of ALHAMBRA were estimated with BPZ2.0, a new version of BPZ (Benítez 2000). The BPZ is a SED-fitting method based in a Bayesian inference, where a maximum likelihood is weighted by a prior probability. The library of 11 SEDs (4 ellipticals, 1 lenticular, 2 spirals, and 4 starbursts) and the prior probabilities used by BPZ2.0 in ALHAMBRA are detailed in Benítez (in prep.). The ALHAMBRA photometry used to compute the photometric redshifts is PSF-matched aperture-corrected and based on isophotal magnitudes. In addition, a recalibration of the zero point of the images was performed to enhance the accuracy of the photometric redshifts. Sources were detected in a synthetic F814W filter image, as noted in the following, defined to resemble the HST/F814W filter. The areas of the images affected by bright stars, as well as those with lower exposure times (e.g., the edges of the images), were masked following Arnalte-Mur et al. (2013). The total area covered by the ALHAMBRA survey after masking is 2.38 deg$^2$. Finally, a statistical star/galaxy separation is encoded in the variable Stellar_Flag of the ALHAMBRA catalogues, and throughout this paper, we keep those ALHAMBRA sources with Stellar_Flag ≤ 0.5 as galaxies.

The photometric redshift accuracy, as estimated by comparison with spectroscopic redshifts ($z_s$), is $\delta z = 0.0108$ at $i \leq 22.5$ with a fraction of catastrophic outliers of $\eta = 2.1\%$. The variable $\delta z$ is the normalized median absolute deviation of the photometric versus spectroscopic redshift distribution (Ilbert et al. 2006; Brammer et al. 2008),

$$\delta z = 1.48 \times \text{median} \left(\frac{|z_p - z_s|}{1 + z_o}\right).$$

The variable $\eta$ is defined as the fraction of galaxies with $|z_p - z_s|/(1 + z_o) > 0.2$. We illustrate the high quality of the ALHAMBRA photometric redshifts in Fig. 2. We refer to Molino et al. (2013) for a more detailed discussion.

The odds quality parameter, as noted $O$, is a proxy for the photometric redshift accuracy of the sources and is also provided by BPZ2.0. The odds is defined as the redshift probability enclosed on a $\pm K(1 + z)$ region around the main peak in the probability distribution function (PDF) of the source, where the constant $K$ is specific for each photometric survey. Molino et al. (2013) find that $K = 0.0125$ is the optimal value for the ALHAMBRA survey. The parameter $O \in [0, 1]$ is related with the confidence of the $z_p$, making it possible to derive high quality samples with better accuracy and lower rate of catastrophic outliers. For example, a $O \geq 0.5$ selection for $i \leq 22.5$ galaxies yields $\delta z = 0.0094$ and $\eta = 1\%$, while $\delta z = 0.0061$ and $\eta = 0.8\%$ for $O \geq 0.9$ (see Molino et al. 2013, for further details). We explore the optimal odds selection in ALHAMBRA for close pair studies in Sect. 4.3.

Reliable photometric redshift errors ($\sigma_{z_p}$) are needed to compute the merger fraction in photometric samples (Sect. 3). In addition to the $z_p$, we have the $z_p^+$ and the $z_p^-$ of each source, which are defined as the redshifts that enclose 68% of the PDF of the source. We estimated the photometric redshift error of each individual source as $\sigma_{z_p} = C \times (z_p^+ - z_p^-)$. The constant $C$ is estimated from the distribution of the variable

$$\Delta z = \frac{z_p - z_s}{\sigma_{z_p}} = \frac{z_p - z_s}{C \times (z_p^+ - z_p^-)}.$$

The variable $\Delta z$ should be normally distributed with a zero mean and unit variance if the values of $\sigma_{z_p}$ from ALHAMBRA are a good descriptor for the accuracy of the photometric redshifts (e.g., Ilbert et al. 2009; Carrasco Kind & Brunner 2013). We find that $\Delta z$ is described well by a normal function when $C = 0.49$ (Fig. 3, see also Molino et al. 2013). With the definition of $z_p^+$ and $z_p^-$, note that $C = 0.5$ was expected. This result also implies that the Gaussian approximation of the PDF assumed in the estimation of the merger fraction (Sect. 3) is statistically valid, even if the actual PDF of the individual sources could be multimodal and/or asymmetric at faint magnitudes. We estimated $C$ for different $i$-band magnitudes and odds selections, finding that the $C$ values are consistent with the global one within ±0.1. Thus, we conclude that $\sigma_{z_p}$ provides a reliable photometric redshift error for every ALHAMBRA source.

To compute close pairs, we defined a principal and a companion sample. The principal sample comprises the more luminous or massive galaxy of the pair, and we looked for those galaxies in the companion sample that fulfil the close pair criterion for each galaxy of the principal sample. If one principal galaxy has more than one close companion, we took each possible pair separately (i.e., if the companion galaxies B and C are close to the principal galaxy A, we study the pairs A–B and A–C as independent). In addition, through this paper, we do not impose any luminosity or mass difference between the galaxies in the close pair unless noted otherwise.

With the previous definitions, the merger fraction is

$$f_m = \frac{N_p}{N_1},$$

where $N_1$ is the number of sources in the principal sample and $N_p$ the number of close pairs. This definition applies to spectroscopic volume-limited samples, but we rely on photometric redshifts to compute $f_m$ in ALHAMBRA. In previous work, López-Sanjuan et al. (2010a) develop a statistical method to obtain reliable merger fractions from photometric redshift catalogues like those from the ALHAMBRA survey. This methodology has been tested with the MGC (López-Sanjuan et al. 2010a) and the VVDS (López-Sanjuan et al. 2012) spectroscopic surveys, and has been successfully applied in the GOODS-South (López-Sanjuan et al. 2010a) and the COSMOS fields (López-Sanjuan et al. 2012). We recall the main points of this methodology below, and we explore how to apply it optimally over the ALHAMBRA data in Sect. 4.3.

We used the following procedure to define a close pair system in our photometric catalogue (see López-Sanjuan et al. 2010a, for details): first, we search for close spatial companions of a principal galaxy with redshift $z_1$ and uncertainty $\sigma_{z_1}$, assuming that the galaxy is located at $z_1 = 2\sigma_{z_1}$. This defines the maximum $\phi$ possible for a given $r_{\text{min}}^p$ in the first instance. If we find a companion galaxy with redshift $z_2$ and uncertainty $\sigma_{z_2}$ at $r_\theta \leq r_{\text{min}}^p$, we study both galaxies in redshift space. For convenience, we assume below that every principal galaxy has, at most, one close companion. In this case, our two galaxies could be a close pair in the redshift range

$$[z^-, z^+] = [z_1 - 2\sigma_{z_1}, z_1 + 2\sigma_{z_1}] \cap [z_2 - 2\sigma_{z_2}, z_2 + 2\sigma_{z_2}].$$

Because of the variation in the range $[z^-, z^+]$ of the function $d_A(z)$, a sky pair at $z_1 = 2\sigma_{z_1}$ might not be a pair at $z_1 + 2\sigma_{z_1}$. We thus impose the condition $r_{\text{min}}^p \leq r_\theta \leq r_{\text{max}}^p$ at all $z \in [z^-, z^+]$ and redefine this redshift interval if the sky pair condition is not satisfied at every redshift. After this, our two galaxies define the close pair system $k$ in the redshift interval $[z^-, z^+]$, where the index $k$ covers all the close pair systems in the sample.

The next step is to define the number of pairs associated to each close pair system $k$. For this, and because all our sources have a photometric redshift, we suppose in the following that a galaxy $i$ in whatever sample is described in redshift space by a Gaussian probability distribution,

$$P_i (z_1 | z_{p,i}, \sigma_{z_{p,i}}) = \frac{1}{\sqrt{2\pi} \sigma_{z_{p,i}}} \exp \left[ -\frac{(z_1 - z_{p,i})^2}{2\sigma_{z_{p,i}}^2} \right].$$

With the previous distribution, we are able to statistically treat all the available information in redshift space and define the number of pairs at redshift $z_1$ in system $k$ as

$$n_k (z_1) = \int_{z_{p,i} - \sigma_{z_{p,i}}}^{z_{p,i} + \sigma_{z_{p,i}}} \int_{z_{p,i} - \sigma_{z_{p,i}}}^{z_{p,i} + \sigma_{z_{p,i}}} P_i (z_1 | z_{p,i}, \sigma_{z_{p,i}}) \, dz_{p,i}. $$

Figure 3. Distribution of the variable $\Delta z$ for the 3813 galaxies in the ALHAMBRA area with $i \leq 22.5$ and a measured spectroscopic redshift. The red line is the best least-squares fit of a Gaussian function to the data. The median, dispersion, and the factor $C$ derived from the fit are labelled in the panel. A colour version of this plot is available in the electronic edition.

**2.2. Sample selection**

Throughout this paper, we focus our analysis on the galaxies in the ALHAMBRA first data release\(^2\). This catalogue comprises ~500k sources and is complete (5.5r, 3′′ aperture) for $i \leq 24.5$ galaxies (Molino et al. 2013). We explored different apparent luminosity sub-samples from $i \leq 23$ to $i \leq 20$. This ensures excellent photometric redshifts and provides reliable merger fraction measurements (Sect. 4.3) because the PDFs of $i \leq 23$ sources are defined well by a single Gaussian peak (Molino et al. 2013). In Sect. 4.7, we also study the cosmic variance in luminosity- and stellar mass-selected samples. The B-band luminosities and the stellar masses of the ALHAMBRA sources were also provided by BPZ2.0 and are included in the ALHAMBRA catalogue (see Molino et al. 2013, for further details). The mass-to-light ratios from Taylor et al. (2011) and a Chabrier (2003) initial mass function were assumed in the estimation of the stellar masses.

**3. Measuring of the merger fraction in photometric samples**

The linear distance between two sources can be obtained from their projected separation, $r_\theta = \phi d_A(z_1)$, and their rest-frame relative velocity along the line of sight, $\Delta v = c|z_2 - z_1|/(1 + z_1)$, where $z_1$ and $z_2$ are the redshift of the principal (more luminous or massive galaxy in the pair) and the companion galaxy, respectively; $\phi$ is the angular separation in arcsec of the two galaxies on the sky plane; and $d_A(z)$ is the angular diameter distance in kpc arcsec$^{-1}$ at redshift $z$. Two galaxies are defined as a close pair if $r_{\text{min}}^p \leq r_\theta \leq r_{\text{max}}^p$ and $\Delta v \leq \Delta v_{\text{max}}$. The PSF of the ALHAMBRA ground-based images is $\lesssim 1''$ (median seeing of $\sim 1''$), which corresponds to 7.6 h$^{-1}$ kpc in our cosmology at $z = 0.9$. To ensure well de-blended sources and to minimise colour contamination, we fixed $r_{\text{min}}^p$ to 10 h$^{-1}$ kpc ($\phi > 1.8''$ at $z \leq 0.9$). We left $r_{\text{max}}^p \leq 50$ h$^{-1}$ kpc as a free parameter and estimate its optimal value in Sect. 4.3. Finally, we set $\Delta v_{\text{max}} = 500$ km s$^{-1}$ by following spectroscopic studies (e.g., Patton et al. 2000; Lin et al. 2008). With the previous constraints, 50%–70% of the selected close pairs finally merge (Patton & Athfield 2008; Bell et al. 2006; Jian et al. 2012).

http://cloud.iaa.es/alhambra/
The final goal of merger studies is the estimation of the merger volume in the sky plane-redshift space. If the primary source is the subindex 1 \([z_1, z_1^\prime]\), the integration limits are

\[
\Delta z_m = z_1 (1 - \Delta z_{\text{max}} / c) - \Delta z_{\text{max}} / c,
\]

\[
\Delta z_{\text{min}} = z_1 (1 + \Delta z_{\text{max}} / c) + \Delta z_{\text{max}} / c,
\]

where \(z_1 \in [z_1, z_1^\prime]\), the integration limits are

\[
\Delta z_m = z_1 (1 - \Delta z_{\text{max}} / c) - \Delta z_{\text{max}} / c,
\]

\[
\Delta z_{\text{min}} = z_1 (1 + \Delta z_{\text{max}} / c) + \Delta z_{\text{max}} / c,
\]

the subindex 1 \([z_1, z_1^\prime]\) refers to the principal [companion] galaxy in the system \(k\), and the constant \(C_k\) normalises the function to the total number of pairs in the interest range.

\[
2N_p^k = \int_{z_1}^{z_1^\prime} \int_{z_1}^{z_1^\prime} P_1(z_1 | z_2, \sigma_{z_1^2}, \sigma_{z_2^2}) \, dz_1 \, dz_2.
\]

Note that \(\Delta z = 0\) if \(z_1 < z_1^\prime\) or \(z_1 > z_1^\prime\). The function \(v_k\) tells us how the number of pairs in the system \(k\), as noted by \(N_p^k\), are distributed in redshift space. The integral in Eq. (6) spans those redshifts in which the companion galaxy has \(\Delta z \leq \Delta z_{\text{max}}\) for a given redshift of the principal galaxy. This translates to \(\Delta z_m - \Delta z_{\text{min}} \approx 0.005\) in our redshift range of interest.

With the previous definitions, the merger fraction in the interval \(z_i = [z_{\text{min}}, z_{\text{max}}]\) is

\[
f_{m} = \frac{\sum_k N_p^k \, v_k (z_i)}{\sum_k N_p^k},
\]

\[
f_{m} = \frac{\sum_k N_p^k \, v_k (z_i)}{N_1},
\]

where \(\sum_k N_p^k\) is analogous to \(N_1\) in Eq. (3). To estimate the observational error of \(f_m\), as noted by \(\sigma_f\), we used the jackknife technique (Efron 1982). We computed partial standard deviations, \(\delta_i\), for each system \(k\) by taking the difference between the measured \(f_m\) and the same quantity with the \(k\)th pair removed for the sample, \(f_m^k\). For a redshift range with \(N_p\) systems, the variance is given by \(\sigma_f^2 = \left[ (N_p - 1) \sum_k \delta_i^2 \right] / N_p\).

3.1. Border effects in redshift and in the sky plane

When we search for a primary source’s companion, we define a volume in the sky-plane-redshift space. If the primary source is near the boundaries of the survey, a fraction of the search volume lies outside of the effective volume of the survey. López-Sanjuan et al. (2010a) find that border effects in the sky plane are representative (i.e., 1σ discrepancy) only at \(r_p^\text{max} \geq 70 h^{-1}\) kpc. Thus, we restricted the search radius in our study to \(r_p^\text{max} \leq 50 h^{-1}\) kpc.

We avoid the incompleteness in redshift space by including the sources in the samples inside the redshift range \([z_{\text{min}}, z_{\text{max}}]\) under study and those sources with either \(z_{p,i} + 2\sigma_{z_p,i} \geq z_{\text{min}}\) or \(z_{p,j} - 2\sigma_{z_p,j} < z_{\text{min}}\).

3.2. The merger rate

The final goal of merger studies is the estimation of the merger rate \(R_m\), defined as the number of mergers per galaxy and Gyr\(^{-1}\). The merger rate is computed from the merger fraction by close pairs as

\[
R_m = \frac{C_m}{T_m} f_m.
\]

The bias of a particular population is usually measured from the analysis of the correlation function and is well established in that the bias increases with luminosity and stellar mass (see e.g., Kitzbichler & White 2008; Lotz et al. 2010a,b; Lin et al. 2010; Jian et al. 2012; Moreno et al. 2013). On the one hand, \(T_m\) depends mainly on the search radius \(r_p^\text{max}\), the stellar mass of the principal galaxy, and the mass ratio between the galaxies in the pair with a mild dependence on redshift and environment (Jian et al. 2012). On the other hand, \(C_m\) depends mainly on \(r_p^\text{max}\) and environment with a mild dependence on both redshift and the mass ratio between the galaxies in the pair (Jian et al. 2012). Despite the efforts in the literature to estimate both \(T_m\) and \(C_m\), different cosmological and galaxy formation models provide different values within a factor of two-three (e.g., Hopkins et al. 2010). To avoid model-dependent results in the present paper, we focus in the cosmic variance of the observational merger fraction \(f_m\).

4. Estimation of the cosmic variance for merger fraction studies

4.1. Theoretical background

In this section, we recall the theoretical background and define the basic variables involved in the cosmic variance definition and characterisation. The relative cosmic variance \(\sigma_R\) arises from the underlying large-scale density fluctuations and leads to variances larger than those expected from simple Poisson statistics. Following Somerville et al. (2004) and Moster et al. (2011), the mean \(\langle N \rangle\) and the variance \(\langle N^2 \rangle - \langle N \rangle^2\) in the distribution of galaxies are given by the first and second moments of the probability distribution \(P_N(V_c)\), which describes the probability of counting \(N\) objects within a volume \(V_c\). The relative cosmic variance is defined as

\[
\sigma_R^2 = \frac{\langle N^2 \rangle - \langle N \rangle^2}{\langle N \rangle} = 1 - \frac{1}{\langle N \rangle}.
\]

The second term represents the correction for the Poisson shot noise. The second moment of the object counts is

\[
\langle N^2 \rangle = \langle N \rangle^2 + \frac{\langle N \rangle^2}{V_c} \int V_c \xi(|r_a - r_d|) dV_{c,a} dV_{c,b},
\]

where \(\xi\) is the two-point correlation function of the sample under study (Peebles 1980). Combining this with Eq. (13), the relative cosmic variance can be written as

\[
\sigma_R^2 = 1 - \frac{1}{V_c} \int V_c \xi(|r_a - r_d|) dV_{c,a} dV_{c,b}.
\]

Thus, the cosmic variance of a given sample depends on the correlation function of that population. We can approximate the galaxy correlation function in Eq. (15) by the linear theory correlation function for dark matter \(\xi_{\text{dm}}\), \(\xi = b^2 \xi_{\text{dm}}\), where \(b\) is the galaxy bias. The bias at a fixed scale depends mainly on both redshift and the selection of the sample under study. With this definition of the correlation function, we find that

\[
\sigma_r \propto b \frac{V_c}{V_1} \sigma_\xi,
\]

where the power law index \(\sigma_\xi\) takes into account the extra volume dependence from the integral of the correlation function \(\xi_{\text{dm}}\) in Eq. (15).

The bias of a particular population is usually measured from the analysis of the correlation function and is well established in that the bias increases with luminosity and stellar mass (see...
In summary, we expect
\[ \sigma_n \propto \frac{b}{V_c} \propto \frac{z^2}{n d^2 V_c^2} \]  \hspace{1cm} (17)

This equation shows that the number density of galaxies, the redshift, and the cosmic volume can be assumed as independent variables in the cosmic variance parametrisation. Equation (17) and the deduction above apply to the cosmic variance in the number of galaxies. We are interested on the cosmic variance of the merger fraction by close pairs, instead, so a dependence on \( V_c \), redshift, and the number density of the two populations under study, as noted by \( n_1 \) for principal galaxies and by \( n_2 \) for the companion galaxies, is expected. We therefore used these four variables \((n_1, n_2, z, V_c)\) to characterise the cosmic variance in close pair studies (Sect. 4.4).

The power-law indices in Eq. (17) could be different for luminosity- and mass-selected samples, as well as for flux-limited samples. In the present paper, we use flux-limited samples selected in the \( i \) band to characterise the cosmic variance. This choice has several benefits, since we have a well-controlled selection function, a better understanding of the photometric redshifts and their errors, and we have access to larger samples at lower redshift that in the luminosity and the stellar mass cases. That improves the statistics and increases the useful redshift range. At the end, future studies will be interested on the cosmic variance in physically selected samples (\( i.e., \) luminosity or stellar mass). Thus, we compare the results from the flux-limited \( i \)-band samples with the actual cosmic variance measured in physically selected samples in Sect. 4.7.

Finally, we set the definition of the number density \( n \). In the present paper, the number density of a given population is the cosmic average number density of that population. For example, if we are studying the merger fraction in a volume dominated by a cluster, we should not use the number density in that volume, but the number density derived from a general luminosity or mass function work instead. Thanks to the 48 sub-fields in ALHAMBRA we have direct access to the average number densities of the populations under study (Sect. 4.4.1).

### 4.2. Distribution of the merger fraction and \( \sigma_v \) estimation

In this section, we explore which statistical distribution reproduces the observed merger fractions better and how to reliably measure the cosmic variance \( \sigma_v \). As representative examples, we show the distributions of the merger fraction \( f_m \) in the 48 ALHAMBRA sub-fields for \( i \leq 22 \) and \( i \leq 21 \) galaxies in Fig. 4. The merger fraction was measured from close pairs with \( 10 \, h^{-1} \text{kpc} \leq r_p \leq 30 \, h^{-1} \text{kpc} \). Unless noted otherwise, the principal and the companion samples in the following comprise the same galaxies. We find that the observed distributions are not Gaussian but follow a log-normal distribution instead,
\[ P_G(f_m|\mu,\sigma) = \frac{1}{\sqrt{2\pi}\sigma f_m} \exp \left( -\frac{(\ln f_m - \mu)^2}{2\sigma^2} \right) \].  \hspace{1cm} (19)

The 68% confidence interval of the log-normal distribution is \([\mu e^{\pm\sigma}, \mu e^{\pm\sigma}]\). This functional distribution was expected for two reasons. First, the merger fraction cannot be negative, implying an asymmetric distribution (Cameron 2011). Second, the distribution of overdense structures in the universe is log-normal \( (\text{e.g., Coles & Jones 1991; de la Torre et al. 2010; Kovač et al. 2010)} \) and the merger fraction increases with density \( (\text{Lin et al. 2010; de Ravel et al. 2011; Kampczyk et al. 2013)} \). We checked that the merger fraction follows a log-normal distribution in all the samples explored in the present paper.

The variable \( \sigma \) encodes the relevant information about the dispersion in the merger fraction distribution, including the dispersion due to the cosmic variance. The study of the median value of the merger fraction in ALHAMBRA, as estimated as \( e^{\mu} \), and its dependence on \( z \), stellar mass, or colour, is beyond the scope of the present paper, and we will address this issue in a future work.

A best least-squares fit with a log-normal function to the distributions in Fig. 4 shows that \( \sigma \) increases with the apparent brightness from \( \sigma = 0.33 \) for \( i \leq 22 \) galaxies to \( \sigma = 0.62 \) for \( i \leq 21 \) galaxies. However, the origin of the observed \( \sigma \) is
twofold: (i) the intrinsic dispersion due to the cosmic variance $\sigma_r$ (i.e., the field-to-field variation in the merger fraction because of the clustering of the galaxies) and (ii) the dispersion due to the observational errors $\sigma_e$, (i.e., the uncertainty in the measurement of the merger fraction in a given field, including the Poisson shot noise term). Thus, the dispersion $\sigma$ reported in Fig. 4 is an upper limit for the actual cosmic variance $\sigma_r$. We deal with this limitation by applying a maximum likelihood estimator (MLE) to the observed distributions. In Appendix A, we develop a MLE that estimates the more probable values of $\mu$ and $\sigma_r$, assuming that the merger fraction follows a Gaussian distribution in log-space (Eq. (19)) that is affected by known observational errors $\sigma_e$. We prove that the MLE provides an unbiased estimation of $\mu$ and $\sigma_r$ and reliable uncertainties of these parameters.

Applying the MLE to the distributions in Fig. 4, we find that $\sigma_r$ is lower than $\sigma_e$ as anticipated, and that the cosmic variance increases with the apparent brightness from $\sigma_r = 0.25 \pm 0.04$ for $i \leq 22$ galaxies to $\sigma_r = 0.44 \pm 0.08$ for $i \leq 21$ galaxies.

We constrain the dependence of $\sigma_r$ on the number density of the populations under study in Sects. 4.4.1 and 4.4.4 on the probed cosmic volume in Sect. 4.4.2 and on redshift in Sect. 4.4.3. That provides a complete description of the cosmic variance for merger fraction studies. We stress that our definition of $\sigma_r$ differs from the classical definition of the relative cosmic variance presented in Sect. 4.1, which is equivalent to $e^{\sigma_r}$. However, $\sigma_r$ encodes the relevant information needed to estimate the intrinsic dispersion in the measurement of the merger fraction due to the clustering of galaxies.

### 4.3. Optimal estimation of $\sigma_r$ in the ALHAMBRA survey

In the previous section, we have defined the methodology to compute the cosmic variance from the observed distribution of the merger fraction. However, as shown by López-Sanjuan et al. (2010a), we need a galaxy sample with either small photometric redshift errors or a large fraction of spectroscopic redshifts to avoid projection effects. In the present study, we did not use information from spectroscopic redshifts, so we should check that the photometric redshifts in ALHAMBRA are good enough for our purposes. A natural way to select excellent photometric redshifts in ALHAMBRA is by a selection in the odds parameter. On the one hand, this selection increases the accuracy of the photometric redshifts of the sample and minimizes the fraction of catastrophic outliers (Molino et al. 2013), improving the merger fraction estimation. On the other hand, our sample becomes incomplete and could be biased toward a population of either bright galaxies or galaxies with marked features in the SED (i.e., emission line galaxies or old populations with a strong 4000 Å break). In this section, we study how the merger fraction in ALHAMBRA depends on the $O$ selection and derive the optimal one to estimate the cosmic variance.

Following the methodology from spectroscopic surveys (e.g., Lin et al. 2004; de Ravel et al. 2009; López-Sanjuan et al. 2011, 2013), if we have a population with a total number of galaxies $N_{\text{tot}}$ in a given volume and we observe a random fraction $f_{\text{obs}}$ of these galaxies, the merger fraction of the total population is

$$f_m = f_{m,\text{obs}} \times f_{\text{obs}}^{-1},$$

where $f_{m,\text{obs}}$ is the merger fraction of the observed sample. In ALHAMBRA, we applied a selection in the parameter $O$, so Eq. (20) becomes

$$f_m = f_m(\geq O_{\text{sel}}) \times \frac{N_{\text{tot}}}{N(\geq O_{\text{sel}})}.$$

where $N(\geq O_{\text{sel}})$ is the number of galaxies with odds higher than $O_{\text{sel}}$ (i.e., galaxies with $O \geq O_{\text{sel}}$). $N_{\text{tot}}$ is the total number of galaxies (i.e., galaxies with $O \geq 0$), and $f_m(\geq O_{\text{sel}})$ is the merger fraction of those galaxies with $O \geq O_{\text{sel}}$. Because $f_m$ must be independent of the $O$ selection, the study of $f_m$ as a function of $O_{\text{sel}}$ provides the clues about the optimal odds selection for merger fraction studies in ALHAMBRA. We show $f_m$ as a function of $O_{\text{sel}}$ for galaxies with $i \leq 22.5$ at $0.3 \leq z < 0.9$ in Fig. 5. We find that

- the merger fraction is roughly constant for $0.2 \leq O_{\text{sel}} \leq 0.6$. This is the expected result if the merger fraction is reliable and measured in a non-biased sample. In this particular case, the $O_{\text{sel}} = 0.2 (0.6)$ sample comprises 98% (66%) of the total number of galaxies with $i \leq 22.5$;
- the merger fraction is overestimated for $O_{\text{sel}} \leq 0.1$. Even if only a small fraction of galaxies with poor constraints in the photometric redshifts are included in the sample, the projection effects become important;
- the merger fraction is overestimated for $O_{\text{sel}} \geq 0.7$. This behaviour at high odds (i.e., in samples with high quality photometric redshifts) suggests that the retained galaxies are a biased sub-sample of the general population under study.

In the analysis above, we only accounted for close companions of $i \leq 22.5$ galaxies with $10 h^{-1}$ kpc $\leq r_p \leq 30 h^{-1}$ kpc, but we can use other values of $r_p^\text{max}$ or searching over different samples. On the one hand, we repeated the study for $r_p^\text{max} = 40$.
and 50 $h^{-1}$ kpc, finding the same behaviour than for $r_{\text{max}} = 30$ $h^{-1}$ kpc (Fig. 5). The only differences are that the merger fraction increases with the search radius and that the $O_{\text{sel}} = 0.2$ point starts to deviate from the expected value (the search area increases with $r_{\text{max}}$ and more accurate photometric redshifts are needed to avoid projection effects). On the other hand, we explored a wide range of i-band magnitude selections from $i \leq 23$ to 20 in the three previous $r_{\text{max}}$ cases. We find again the same behaviour. That reinforces our arguments above and suggests $0.3 \leq O_{\text{sel}} \leq 0.6$ as acceptable odds limits to select samples for merger fraction studies in ALHAMBRA.

The merger fraction increases with the search radius (Fig. 5). However, the merger rate $R_m$ (Sect. 3.2) is a physical property of any population, and it cannot depend on $r_{\text{max}}$. Thus, the increase in the merger fraction with the search radius is compensated with the increase in the merger time scale (e.g., de Ravel et al. 2009; L&ópez-Sanjuan et al. 2011). This is, $R_m \propto f_m(r_{\text{max}})/T_m(r_{\text{max}})$. For the same reason, the cosmic variance of the merger rate cannot depend on $r_{\text{max}}$. In other words, the 68% confidence interval of the merger rate, $[R_m e^{-\sigma_r}, R_m e^{\sigma_r}]$, should be independent of the search radius. Expanding the previous confidence interval, we find that

$$[R_m e^{-\sigma_r}, R_m e^{\sigma_r}] \propto \left[ f_m(r_{\text{max}}) T_m^{-1}(r_{\text{max}}) e^{-\sigma_T}, f_m(r_{\text{max}}) T_m^{-1}(r_{\text{max}}) e^{\sigma_T} \right] = \left[ f_m(r_{\text{max}}) e^{-\sigma_r}, f_m(r_{\text{max}}) e^{\sigma_r} \right] T_m^{-1}(r_{\text{max}}).$$

Note that the dependence on $r_{\text{max}}$ is encoded in the median merger fraction and in the merger time scale. Thus, the cosmic variance $\sigma_r$ of the merger fraction should not depend on the search radius. We checked this prediction by studying the cosmic variance as a function of the search radius for $i \leq 22.5$, 21.5, and 21 galaxies with $O \geq O_{\text{sel}} = 0.3$ at $0.3 \leq z < 0.9$. We find that $\sigma_r$ is consistent with a constant value irrespective of $r_{\text{max}}$ in the three populations probed, as desired (Table 2 and Fig. 6). This supports $\sigma_r$ as a good descriptor of the cosmic variance and our methodology to measure it. In the previous analysis, we have omitted the merger probability $C_m$, which mainly depends on $r_{\text{max}}$ and environment (Sect. 3.2). The merger fraction correlates with environment, so the merger probability could modify the factor $e^{\sigma_T}$ in Eq. (22). Because a constant $\sigma_r$ with $r_{\text{max}}$ is observed, the impact of $C_m$ in the $f_m$ to $R_m$ translation should be similar in the range of $r_{\text{max}}$ explored. Detailed cosmological simulations are needed to clarify this issue.

Finally, we studied the dependence of $\sigma_r$ on the odds selection for $i \leq 22.5$ galaxies at $0.3 \leq z < 0.9$. Following the same arguments than before, the cosmic variance should not depend on the odds selection. We find that (i) $\sigma_r$ is consistent with a constant value as a function of $r_{\text{max}}$ for any $O_{\text{sel}}$, reinforcing our results above; and (ii) $\sigma_r$ is independent of the odds selection at $0.1 \leq O_{\text{sel}} \leq 0.5$ (Fig. 7). As for the merger fraction, we checked that different populations follow the same behaviour. We therefore set $O \geq O_{\text{sel}} = 0.3$ as the optimal odds selection to measure the cosmic variance in ALHAMBRA. This selection provides excellent photometric redshifts and ensures representative samples.

In summary, we estimate the cosmic variance $\sigma_r$ from the merger fractions measured in the 48 ALHAMBRA sub-fields with 10 $h^{-1}$ kpc $\leq r_p \leq 50$ $h^{-1}$ kpc close pairs (the $\sigma_r$ uncertainty is lower for larger search radii) and in samples with $O \geq O_{\text{sel}} = 0.3$ in the following. That ensures reliable results in representative (i.e., non-biased) samples.

### 4.4. Characterisation of $\sigma_r$

At this stage, we have set both the methodology to compute a robust cosmic variance from the observed merger fraction distribution (Sect. 4.2) and the optimal search radius and odds selection to estimate $\sigma_r$ in ALHAMBRA (Sect. 4.3). Now, we can characterise the cosmic variance as a function of the populations under study (Sects. 4.4.1 and 4.4.4), the probed cosmic volume (Sect. 4.4.2), and the redshift (Sect. 4.4.3).

#### 4.4.1. Dependence on the number density of the principal sample

In this section, we explore how the cosmic variance depends on the number density $n_1$ of the principal population under study. For that, we took the same population as principal and companion sample. We study the dependence on the companion sample in Sect. 4.4.4. To avoid any dependence of $\sigma_r$ on either the probed cosmic volume and $z$ and to minimise the observational errors, we focus on the redshift range $0.3 \leq z < 0.9$ in this section. This range probes a cosmic volume of $V_c \sim 1.4 \times 10^5$ Mpc$^3$ in each ALHAMBRA sub-field. To explore different number
We estimated the average number density $n_i$ of the principal sample under study. Increasing the number density, the principal sample comprises $i \leq 20, 20.5, 21, 21.5, 22, 22.5,$ and 23 galaxies, respectively. The probed cosmic volume is the same in all the cases, $V_c \sim 1.4 \times 10^5$ Mpc$^3$ (0.3 $\leq z < 0.9$). The dashed line is the error-weighted least-squares fit of a power-law to the data, $\sigma_v \propto n_i^{-0.54}$. A colour version of this plot is available in the electronic edition.

Cosmic variance $\sigma_v$ as a function of the number density $n_i$ of the principal sample. The probed cosmic volume is the same in all the cases, $V_c \sim 1.4 \times 10^5$ Mpc$^3$ (0.3 $\leq z < 0.9$). The dashed line is the error-weighted least-squares fit of a power-law to the data, $\sigma_v \propto n_i^{-0.54}$. A colour version of this plot is available in the electronic edition.

In this section, we explore the dependence of the cosmic variance on the probed cosmic volume by fitting the two sets of data (variation in redshift and area) separately. We find $\sigma_v^* \propto V_c^{-0.43 \pm 0.08}$ for the redshift data, while $\sigma_v^* \propto V_c^{-0.48 \pm 0.05}$ for the area data.

4.4.2. Dependence on the cosmological volume

We tested the robustness of our result by fitting the two sets of data (variation in redshift and area) separately. We find $\sigma_v^* \propto V_c^{-0.43 \pm 0.08}$ for the redshift data, while $\sigma_v^* \propto V_c^{-0.48 \pm 0.05}$ for the area data.

4.4.3. Dependence on redshift

The redshift is an expected parameter in the parametrisation the cosmic variance. However, Fig. 9 shows that the results at different redshifts are consistent with those from the wide redshift range 0.3 $\leq z < 0.9$. As a consequence, the redshift dependence of the cosmic variance should be smaller than the typical error in our measurements. We tested this hypothesis by measuring $\sigma_v$ in different, non-overlapping redshift bins. We summarise our measurements, as performed for $i \leq 23$ galaxies, in Table 5. We defined $\sigma_{v^*} = \sigma_i / \sigma_v(n_i, V_c)$ for the redshift dependence of the cosmic variance. We find that $\sigma_{v^*}$ is compatible with unity, $\sigma_{v^*} = 1.02 \pm 0.07$, and that no redshift dependence remains after accounting for the variation in $n_i$ and $V_c$ (Fig. 10). This confirms our initial hypothesis and we assume, therefore, $y = 0$ in the following.
4.4.4. Dependence on the number density of the companion sample

As we show in Sect. 3, two different populations are involved in the measurement of the merger fraction: the principal sample and the sample of companions around principal galaxies. In the previous sections, the principal and the companion sample were the same, and here we explore how the number density \(n_c\) of the companion sample impacts the cosmic variance. We set \(i \leq 20.5\) galaxies at \(0.3 \leq z < 0.9\) as principals and varied the \(i\)-band selection of the companion galaxies from \(i \geq 20.5\) to \(i \leq 23\) in 0.5 steps. As in Sect. 4.4.2, the variable \(\sigma_{\nu}^* = \sigma_{\nu}/\sigma_{\nu}(n_1)\) was used.

We find that the cosmic variance decreases as the number density of the companion sample increases (Table 6 and Fig. 11). We fit the dependence with a power-law, forcing it to pass for the point \(\sigma_{\nu}^*(n_1, n_1) = 1\). We find that

\[
\sigma_{\nu}^*(n_1, n_2) = \left(\frac{n_2}{n_1}\right)^{-0.37 \pm 0.04}. \tag{26}
\]

We checked that it is consistent with unity if we leave free the intercept, as we assume \(\sigma_{\nu}^*(n_1, n_1) = 1.04 \pm 0.12\). In addition, the power-law index changes slightly, \(\sigma_{\nu}^* \propto (n_2/n_1)^{-0.39 \pm 0.08}\).

4.4.5. The cosmic variance in merger fraction studies based on close pairs

In the previous sections, we have characterised the dependence of the cosmic variance \(\sigma_{\nu}\) on the basic parameters involved in close pair studies (Sect. 4.1): the number density of the principal \((n_1, \text{Sect. 4.4.1})\) and the companion sample \((n_2, \text{Sect. 4.4.4})\), the
cubic cosmic volume under study \( (V_c, \text{Sect. 4.4.2}) \), and the redshift (Sect. 4.4.3). We find that

\[
\sigma_v(n_1, n_2, V_c) = 0.48 \times \left( \frac{n_1}{10^3 \text{ Mpc}^{-3}} \right)^{-0.54} \times \left( \frac{V_c}{10^5 \text{ Mpc}^3} \right)^{-0.48} \times \left( \frac{n_2}{n_1} \right)^{-0.37}.
\]  

(27)

This is the main result of the present paper. We estimated through Monte Carlo sampling that the typical uncertainty in \( \sigma_v \) from this relation is \( \sim 15\% \). The dependence of \( \sigma_v \) on redshift should be lower than this uncertainty. In addition, \( \sigma_v \) is independent of the search radius used to compute the merger fraction as we demonstrated in Sect. 4.3.

### 4.5. Cosmic variance in spatially random samples

In this section, we further test the significance of our results by measuring both the merger fraction and the cosmic variance in samples randomly distributed in the sky plane. For this, we created a set of 100 random samples with each random sample comprising 48 random sub-samples (one per ALHAMBRA sub-field). We generated each random sub-sample by assigning a random RA and Dec to each source in the original catalogue but retained the original redshift of the sources. This erases the clustering signal inside each ALHAMBRA sub-field (i.e., at \( \lesssim 15' \) scales), but the number density fluctuations between sub-fields because of the clustering at scales larger than \( \sim 15' \) remains. We estimated the merger fraction and the cosmic variance for each random sample at \( 0.3 \leq z < 0.9 \) as in Sect. 4.4.1, computed the median merger fraction, \( \langle f_m \rangle \), and determined the median cosmic variance, \( \langle \sigma_v \rangle \), in the set of 100 random samples to compare them with the values measured in the real samples. To facilitate this comparison, we defined the variables \( F_m = f_m / \langle f_m \rangle \) and \( \Sigma_v = \sigma_v / \langle \sigma_v \rangle \). We estimated \( F_m \) and \( \Sigma_v \) for different selections in \( n_1 \) following Sect. 4.4.1, and we have show our findings in Fig. 12.

On the one hand, the merger fraction in the real samples is higher than in the random samples by a factor of three–four, \( F_m = 4.25 \times 0.27 \times n_1 \) (Fig. 12, top panel). This reflects the clustering present in the real samples that we erased when we randomised the positions of the sources in the sky, as well as the higher clustering of more luminous galaxies. This result is consistent with previous close pair studies that compare real and random samples (e.g., Kartaltepe et al. 2007). On the other hand, the cosmic variance measured in the random samples is higher than the cosmic variance in the real ones, \( \Sigma_v = 0.81 \pm 0.04 \) (Fig. 12, bottom panel). This implies that most of the variance between sub-fields is unrelated with the clustering inside these sub-fields and that the \( \sigma_v \) measured in the present paper is a real signature of the relative field-to-field variation of the merger fraction.

### 4.6. Testing the independence of the 48 ALHAMBRA sub-fields

Hitherto, we have assumed that the 48 ALHAMBRA sub-fields are independent. However, only the seven ALHAMBRA
the seven independent pointings of each group, and we obtained $\sigma_v^{**} = 1.01 \pm 0.10$ for the first (circles) and the second (triangles) group of seven independent pointings in the ALHAMBRA survey (see text for details). The dashed line marks the error-weighted average of $\sigma_v^{**}$, and the coloured area shows its 68% confidence interval. A colour version of this plot is available in the electronic edition.

We find that the cosmic variance from the seven independent areas is described well by the approximation to study $\sigma_v$. Finally, we defined $\sigma_v^{**}$ as a function of $n_1$ for samples selected in stellar mass. The dots are those samples without a mass ratio imposed, and the squares are with a mass ratio applied (Table 9). Points at the same number density are offset when needed to avoid overlap. The dashed line marks the error-weighted average of $\sigma_v^{**}$, and the coloured area shows its 68% confidence interval. The grey area marks the 15% uncertainty expected from our parametrisation of the cosmic variance. A colour version of this plot is available in the electronic edition.

fields are really independent and correlations between adjacent sub-fields should exist. This correlations could impact our $\sigma_v$ measurements, and in this section, we test the independence assumption.

We defined two groups of seven independent pointings with one per ALHAMBRA field. The first group comprises of the pointings f02p01, f03p02, f04p01, f05p01, f06p01, f07p03, and f08p02, where f0? refers to the ALHAMBRA field and p0? to the pointing in the field. The second group comprises the pointings f02p02, f03p01, f04p01, f05p01, f06p02, f07p04, and f08p01. Note that fields f04 and f05 have only one pointing in the current ALHAMBRA release. Each of the previous pointings probe a cosmic volume four times higher than our fiducial sub-fields with a median $V_c = (54.49 \pm 0.59) \times 10^4$ Mpc$^3$ for the first group and $V_c = (55.24 \pm 0.50) \times 10^4$ Mpc$^3$ for the second one at $0.3 \leq z < 0.9$. Finally, we measured the merger fraction in the seven independent pointings of each group, and we obtained $\sigma_v$ applying the MLE. We repeated this procedure for different selections from $i \leq 23$ to $i \leq 20.5$ in 0.5 magnitude steps. Finally, we defined $\sigma_v^{**} = \sigma_v/(n_1, V_c)$, so the values of $\sigma_v^{**}$ would be dispersed around unity if the cosmic variance measured from the seven independent areas is described well by the cosmic variance measured from the 48 sub-fields. We summarise our results in Table 7 and in Fig. 13.

We find that the cosmic variance from the seven independent fields nicely agree with our expectations from Eq. (27) with an error-weighted average of $\sigma_v^{**} = 1.01 \pm 0.10$. Thus, assuming the 48 ALHAMBRA sub-fields as independent is an acceptable approximation to study $\sigma_v$. In addition, the uncertainties in $\sigma_v$ are lower by a factor of two when we use the 48 sub-fields, improving the statistical significance of our results.
4.7. Expectations for luminosity- and mass-selected samples

Throughout this paper, we have focused our analysis in (apparent) bright galaxies with $i \leq 23$. This ensures excellent photometric redshifts and provides reliable merger fraction measurements (Sect. 4.3). However, one should be interested on the merger fraction of galaxies selected by their luminosity, stellar mass, colour, etc. Because the bias of the galaxies with respect to the underlying dark-matter distribution depends on the selection of the sample, our prescription to estimate $\sigma_\epsilon$ could not be valid for physically selected samples (Sect. 4.1). In this section, we compare the expected cosmic variance from Eq. (27) with the actual cosmic variance of several luminosity- and stellar mass-selected samples to set the limits and the reliability of our suggested parametrisation.

We defined the variable $\sigma_\epsilon^{*\ast} = \sigma_\epsilon/\sigma_\epsilon(n_1, n_2, V_c)$, so the values of $\sigma_\epsilon^{*\ast}$ would be dispersed around unity if no extra dependence on the luminosity or the stellar mass exists. Throughout the present paper, we employed neither luminosity nor mass ratio constraints between the galaxies in the close pairs. However, merger fraction studies impose such constraints to study major or minor mergers. This ratio is defined as $R = M_{*+2}/M_{*+1}$, where $M_{*+1}$ and $M_{*+2}$ are the stellar masses of the principal and the companion galaxy in the pair, respectively. The definition of $R$ in the $B$-band luminosity $L_B$ case is similar. Major mergers are usually defined with $1/4 \leq R \leq 1$, while minor mergers with $R \leq 1/4$. We explored different $R$ cases and estimated $n_2$ as the number density of the $L_B \geq R L_B,1$ or the $M_* \geq R M_{*},1$ population. The properties of all the studied samples are summarised in Tables 8 and 9. The redshift range probed in each case was chosen to ensure volume-limited companion samples. We stress that the samples in Tables 8 and 9 mimic typical observational selections and $R$ values from the literature.

On the other hand, we find that the error-weighted average of all the luminosity-selected samples is $\sigma_\epsilon^{*\ast} = 1.01 \pm 0.03$, which is compatible with unity as we expected, if no (or limited) dependence on the selection exists (Fig. 14). We obtained $\sigma_\epsilon^{*\ast} = 1.03 \pm 0.05$ from samples with the luminosity ratio $R$ applied, while $\sigma_\epsilon^{*\ast} = 1.00 \pm 0.03$ from samples without it. On the other hand, we find $\sigma_\epsilon^{*\ast} = 1.02 \pm 0.03$ for the stellar mass-selected samples (Fig. 15). As noted previously, the value is compatible with unity. We obtained $\sigma_\epsilon^{*\ast} = 0.98 \pm 0.05$ from samples with the mass ratio $R$ applied, while $\sigma_\epsilon^{*\ast} = 1.03 \pm 0.03$ from samples without it.

We conclude that our results based on $i$-band selected samples provide a good description of the cosmic variance for physically selected samples with a limited dependence ($\leq 15\%$) on both the luminosity and the stellar mass selection. Thus, only $n_1$, $n_2$, and $V_c$ are needed to estimate a reliable $\sigma_\epsilon$ for merger fractions studies based on close pairs.

5. Summary and conclusions

We use the 48 sub-fields of $\sim 180$ arcmin$^2$ in the ALHAMBRA survey (total effective area of 2.38 deg$^2$) to empirically estimate the cosmic variance that affects merger fraction studies based on close pairs in the first time in the literature. We find that the distribution of the merger fraction is log-normal, and we use a maximum likelihood estimator to measure the cosmic variance $\sigma_\epsilon$ unaffected by observational errors (including the Poisson shot noise term).

We find that the better parametrisation of the cosmic variance for merger fraction studies based on close pairs is (Eq. (27)),

$$
\sigma_\epsilon(n_1, n_2, V_c) = 0.48 \times \left(\frac{n_1}{10^{-3} \text{Mpc}^{-3}}\right)^{-0.54} \times \left(\frac{V_c}{10^8 \text{Mpc}^3}\right)^{-0.48} \times \left(\frac{n_2}{n_1}\right)^{-0.37},
$$
where \( n_1 \) and \( n_2 \) are the average number density of the principal and the companion populations under study, respectively, and \( V_c \) is the cosmological volume probed by our survey in the redshift range of interest. We stress that \( n_1 \) and \( n_2 \) should be estimated from general luminosity or mass function studies and that measurements from volumes dominated by structures (e.g., clusters or voids) should be avoided. In addition, \( \sigma_\nu \) is independent of the search radius used to compute the merger fraction.

The typical uncertainty in \( \sigma_\nu \) from our relation is \( \sim 15\% \). The dependence of the cosmic variance on redshift should be lower than this uncertainty. Finally, we checked that our formula provides a good estimation of \( \sigma_\nu \) for luminosity- and mass-selected samples and for close pairs with a given luminosity or mass ratio \( \mathcal{R} \) between the galaxies in the pair. In the latter case, \( n_2 \) is the average number density of those galaxies brighter or more massive than \( \mathcal{R} n_1 \) or \( \mathcal{R} M_\ast \), respectively.

Equation (27) provides the expected cosmic variance of an individual merger fraction measurement \( f_m \) at a given field and redshift range. The 68% confidence interval of this merger fraction is \( [f_{m1}, f_{m2}] \). This interval is independent of the error in the measurement of \( f_m \), so both sources of uncertainty should be added to obtain an accurate description of the merger fraction error in pencil-beam surveys. If we have access to several independent fields \( j \) for our study, we should combine the cosmic variance \( \sigma_{\nu,\text{tot}}^2 \) of each single field with the following formula (see Moster et al. 2011, for details):

\[
\sigma_{\nu,\text{tot}}^2 = \frac{\sum (V_j^i / \sigma_j^2)^2}{\sum (V_j^i)^2}, \tag{28}
\]

where \( V_j^i \) is the cosmic volume probed by each single field in the redshift range of interest.

Thanks to the Eqs. (27) and (28), we can estimate the impact of cosmic variance in close pair studies from the literature. For example, Bundy et al. (2009) measure the major merger fraction in the two GOODS fields. We expect \( \sigma_\nu \sim 0.42 \) for massive \( (M_\ast \gtrsim 10^{11} M_\odot) \) galaxies, while \( \sigma_\nu \lesssim 0.16 \) for \( M_\ast \gtrsim 10^{10} M_\odot \) galaxies. The studies of de Ravel et al. (2009) and López-Sanjuan et al. (2011) explore the merger fraction in the VVDS-Deep. We expect \( \sigma_\nu \lesssim 0.09 \) for major mergers and \( \sigma_\nu \lesssim 0.07 \) for minor mergers in this survey. Lin et al. (2008) explore the merger properties of \( M_\ast \lesssim 10^9 \) galaxies in three DEEP2 fields. We estimate \( \sigma_\nu \sim 0.03 \) for their results. Several major close pair studies have been conducted in the COSMOS field (e.g., de Ravel et al. 2011; Xu et al. 2012). Focusing in mass-selected samples, we expect \( \sigma_\nu \sim 0.17 \) for massive galaxies, while \( \sigma_\nu \sim 0.07 \) for \( M_\ast \gtrsim 10^{10} M_\odot \) galaxies. In addition, we estimate \( \sigma_\nu \sim 0.13 \) for the minor merger fractions reported by López-Sanjuan et al. (2012) in the COSMOS field. Regarding local merger fractions \( (z \lesssim 0.1) \), the expected cosmic variance in the study of De Propris et al. (2005) in the MGC is \( \sigma_\nu \sim 0.03 \), while it is \( \sigma_\nu < 0.05 \) in the study of Patton et al. (2000). Finally, studies based in the full SDSS area are barely affected by cosmic variance with \( \sigma_\nu \lesssim 0.005 \) (e.g., Patton & Athfield 2008).

Extended samples over larger sky areas are needed to constrain the subtle redshift evolution of the cosmic variance and its dependence on the selection of the samples. Future large photometric surveys such as J-PAS (Javalambre – Physics of the accelerating universe Astrophysical Survey, Benítez et al. 2014), which will provide excellent photometric redshifts with \( \delta_z \lesssim 0.003 \) over 8500 deg\(^2\) in the northern sky, are fundamental to progress on this topic.

In the present paper, we have studied the intrinsic dispersion of the merger fraction measured in the 48 ALHAMBRA...
sub-fields in detail. In future papers, we will explore the dependence of the \textit{median} merger fraction, as estimated as $e^e$, on stellar mass, colour, or morphology (see Pović et al. 2013, for details about the morphological classification in ALHAMBRA), and we will compare the ALHAMBRA measurements (both the median and the dispersion) to the expectations from cosmological simulations.

Acknowledgements. We dedicate this paper to the memory of our six IAC colleagues and friends who met with a fatal accident in Piedra de los Cochinos, Tenerife, in February 2007, with a special thanks to Maurizio Pannizzo, whose teachings of python were so important for this paper. We thank the comments and suggestions of the anonymous referee, that improved the clarity of the manuscript. This work has mainly been funding by the FITE (Fondo de Inversiones de Teruel) and the projects AYA2010-15169, AYA2010-22111-C03-01 and AYA2010-22111-C03-02, from the Junta de Andalucía through TIC-114 and the Excellence Project P08-TIC-03531, and from the Generalitat Valenciana through the project Prometeo/2009/064. A.J.C. (RyC-2011-08529) and C.H. (RyC-2011-08262) are Ramón y Cajal fellows of the Spanish government.

Appendix A: Maximum likelihood estimation of the cosmic variance $\sigma'_{\nu}$

Maximum likelihood estimators (MLEs) have been used in a wide range of topics in astrophysics. For example, Naylor & Jeffries (2006) used a MLE to fit colour-magnitude diagrams, Arzner et al. (2007) to improve the determination of faint X-ray spectra, Makarov et al. (2006) to improve distance estimates using red giant branch stars, and López-Sanjuan et al. (2008, 2009a,b, 2010b) to estimate reliable merger fractions from morphological criteria. The MLEs are based on the estimation of the most probable values of a set of parameters, which define the probability distribution that describes an observational sample.

The general MLE operates as follows. Throughout this Appendix, we denote the probability to obtain the values $a$ given the parameters $b$ as $P(a|b)$. Being $x_j$ the measured values in the ALHAMBRA field $j$, and $\theta$ the parameters that we want to estimate, we may express the joined likelihood function as

$$L(x_j | \theta) \equiv - \ln \left[ \prod_j P(x_j | \theta) \right] = - \sum_j \ln \left[ P(x_j | \theta) \right]. \quad (A.1)$$

If we are able to express $P(x_j | \theta)$ analytically, we can minimise Eq. (A.1) to obtain the best estimation of the parameters $\theta$, as denoted as $\theta_{\text{ML}}$. In our case, $x_j$ is the observed value of the merger fraction in log-space for the ALHAMBRA sub-field $j$, where $x_j \equiv f'_{\text{real},j} = \ln f_m$. We decided to work in log-space because that makes the problem analytic and simplifies the implementation of the method without losing mathematical rigour.

The ALHAMBRA sub-fields are assumed to have a real distribution that describes an observational sample. Thus, we estimated the observational errors in log-space as $\sigma'_{\nu,\text{real}}$, which are unaffected by observational errors.

In addition, we can analytically estimate the errors in the parameters above. We can obtain those via an expansion of the function $L(f'_{\text{real},j} | \mu, \sigma_{\nu,\text{o}}, \sigma_{\theta,\text{o}})$ in a Taylor’s series of its variables $\theta = (\mu, \sigma_{\nu,\text{o}}, \sigma_{\theta,\text{o}})$ around the minimisation point $\theta_{\text{ML}}$. The previous minimisation process made the first $L$ derivative null, and we obtain

$$L = L(\theta_{\text{ML}}) + \frac{1}{2} (\theta - \theta_{\text{ML}})^T H_{\text{yy}} (\theta - \theta_{\text{ML}}), \quad (A.6)$$

where $H_{\text{yy}}$ is the Hessian matrix, and $T$ denotes the transpose matrix. The inverse of the Hessian matrix provides an estimate of the 68% confidence intervals of $\mu_{\text{ML}}$ and $\sigma_{\text{ML}}$, as well as the covariance between them. The Hessian matrix of the joined likelihood function $L$ is defined as

$$H_{\text{yy}} = \left( \frac{\partial^2 L}{\partial \mu \partial \sigma_{\theta,\text{o}}} \right), \quad (A.7)$$

with

$$\frac{\partial^2 L}{\partial \mu} = \sum_i \frac{1}{\sigma_{\theta,\text{o}}^2}. \quad (A.8)$$

and

$$\frac{\partial^2 L}{\partial \sigma_{\theta,\text{o}}} = \frac{\partial^2 L}{\partial \mu} \frac{\partial \mu}{\partial \sigma_{\theta,\text{o}}} = -2 \sum_i \sigma_{\theta,\text{o}} \frac{\partial f'_{\text{real},j}}{\partial \mu} \frac{\partial \mu}{\partial \sigma_{\theta,\text{o}}}. \quad (A.9)$$

Then, we computed the inverse of the minus Hessian, $h_{\text{yy}} = (-H_{\text{yy}})^{-1}$. Finally, we estimated the variances of our inferred parameters as $\sigma_{\mu,\text{r}} = h_{11}$ and $\sigma_{\sigma_{\nu,\text{o}},\sigma_{\theta,\text{o}}} = h_{22}$ because maximum likelihood theory states that $\sigma_{\theta,\text{o}}^2 \leq h_{11}$. We tested the performance and the limitations of our MLE through synthetic catalogues of merger fractions. We created several sets of 1000 synthetic catalogues with each of them composed by a number $n$ of merger fractions randomly drawn from a log-normal distribution with $\mu = 0.05$ and $\sigma_{\text{r,\text{in}}} = 0.2$ and affected by observational errors $\sigma_\nu$. We explored the $n = 50$, 250 and 1000 cases for the number of merger fractions and varied the observational errors from $\sigma_\nu = 0.1$ to 0.5 in 0.1 steps. That is, we explored observational errors in the measurement of the merger fraction from $\Delta \sigma \equiv \sigma_\nu/\sigma_\nu = 0.5$ to 2.5 times the cosmic
Fig. A.1. Recovered cosmic variance over input cosmic variance (top panel) and median $\sigma_{\nu}$ over the dispersion of the recovered cosmic variance (bottom panel) as a function of $\Delta \sigma$. In both panels, triangles, circles, and squares are the results from synthetic catalogues with $n = 50, 250$, and $1000$, respectively. White symbols show the results from the BLS fit to the data ($\sigma_{\nu,\text{BLS}}$), while those coloured show the ones from the MLE ($\sigma_{\nu,\text{ML}}$). The $n = 50$ and $1000$ points are shifted to avoid overlap. The dashed lines mark identity, and the solid line in the top panel shows the expectation from a convolution of two Gaussians in log-space, $\sigma_{\nu,\text{BLS}}/\sigma_{\nu,\text{in}} = \sqrt{1 + (\Delta \sigma)^2}$.

The variance that we want to measure. We checked that the results below are similar for any value of $\sigma_{\nu,\text{in}}$. We find that
1. The median value of the recovered $\mu$, as noted $\overline{\mu}_{\text{ML}}$, in each set of synthetic catalogues is similar to $\mu_{\text{in}}$, with deviations lower than 0.5% in all cases under study. However, we find that $\overline{\sigma}_{\nu,\text{ML}}$ for $n = 50$ catalogues overestimates $\sigma_{\nu,\text{in}}$ more than 5% at $\Delta \sigma \gtrsim 2.0$, while we recover $\sigma_{\nu,\text{in}}$ well even with $\Delta \sigma = 2.5$ (Fig. A.1, top panel) for $n = 1000$. This means that larger data sets are needed to recover the underlying distribution as the observational errors increase.
2. We also study the values recovered by a best least-squares (BLS) fit of Eq. (18) to the synthetic catalogues. We find that (i) the BLS fit recovers the right values of $\mu_{\text{in}}$. This was expected, since the applied observational errors preserve the median of the initial distribution. (ii) The BLS fit overestimates $\sigma_{\nu,\text{in}}$ in all cases. The recovered values depart from the initial one as expected from a convolution of two Gaussians with a variance $\sigma_{\nu,\text{in}}$ and $\sigma_{\nu}$, where $\sigma_{\nu,\text{BLS}}/\sigma_{\nu,\text{in}} = \sqrt{1 + (\Delta \sigma)^2}$. The MLE performs a de-convolution of the observational errors, recovering accurately the initial cosmic variance (Fig. A.1, top panel).
3. The estimated variances of $\mu$ and $\sigma_{\nu}$ are reliable. That is, the median variances $\overline{\sigma}_{\nu}$ and $\overline{\sigma}_{\nu}$ estimated by the MLE are similar to the dispersion of the recovered values, as noted $s_{\nu}$ and $s_{\nu}$, in each set of synthetic catalogues. The difference between both variances for $\mu$ is lower than 5% in all the probed cases. However, we find that $\overline{\sigma}_{\nu}$ for $n = 50$ catalogues overestimates $s_{\nu}$, which is more than 5% at $\Delta \sigma \gtrsim 1.5$: this is the limit of the MLE to estimate reliable uncertainties with this number of data (Fig. A.1, bottom panel). Because the estimated variance tends asymptotically to $s_{\nu}$, for a large number of data, $\overline{\sigma}_{\nu}$ for $n = 1000$ catalogues deviates less from the expected value than for $n = 50$ synthetic catalogues. Note that the value of $\sigma_{\nu}$ is still unbiased as such large observational errors (Fig. A.1, top panel), while the estimated variance $\sigma_{\nu}$ deviates from the expectations at large $\Delta \sigma$, and we can roughly estimate $\sigma_{\nu}$ through realistic synthetic catalogues as those in this Appendix.
4. The variances of the recovered parameters decreases with $n$ and increases with $\sigma_{\nu}$. That reflects the loss of information due to the observational errors. Remark that the MLE takes these observational errors into account to estimate the parameters and their variance.

We conclude that the MLE developed in this Appendix is not biased, providing accurate variances, and we can recover reliable uncertainties of the cosmic variance $\sigma_{\nu}$ in ALHAMBRA ($n = 48$) for $\Delta \sigma \leq 1.5$. Note that reliable values of $\sigma_{\nu}$ in ALHAMBRA are recovered at $\Delta \sigma \lesssim 2.0$. We checked that the average $\Delta \sigma$ in our study is 0.60 (the average observational error is $\overline{\sigma}_{\nu} = 0.18$), and the maximum value is $\Delta \sigma = 0.85$. Thus, the results in the present paper are robust against the effect of observational errors.
