Supporting Information

ABSTRACT: We report on the numerical analysis of solar absorption enhancement in organic–inorganic halide perovskite films embedding plasmonic gold nanoparticles. The effect of particle size and concentration is analyzed in realistic systems in which random particle location within the perovskite film and the eventual formation of dimers are also taken into account. We find a maximum integrated solar absorption enhancement of ∼10% in perovskite films of 200 nm thickness and ∼6% in 300 nm films, with spheres of radii 60 and 90 nm, respectively, in volume concentrations of around 10% in both cases. We show that the presence of dimers boosts the absorption enhancement up to ∼12% in the thinnest films considered. Absorption reinforcement arises from a double contribution of plasmonic near-field and scattering effects, whose respective weight can be discriminated and evaluated from the simulations.

1. INTRODUCTION

Since the emergence of organic–inorganic halide perovskite solar cells,1,2 different synthetic approaches have been explored to improve their performance.3,4 Efforts have been put into controlling the composition6–7 or structural ordering8 of perovskite films, as well as to provide the solar cells made out of them with other attractive properties apart from their high efficiency, such as flexibility,9 transparency,8 and color.10 Also, motivated from the environmental issues related to the use of heavy metals, the viability of lead-free variants has been tested.11,12

From a different perspective, recent analysis of the optical response of these photovoltaic systems13–15 has shown that light collection at long wavelengths (∼650, 800 nm) is not optimized, opening a new route to increase the performance of the device. Contrarily to what happened in other dye-sensitized clusters of irregular or planar shapes.22,23 In all cases, cell performance enhancements are observed, although the potential contribution of near-field enhancement effects is largely diminished or excluded, as the metal particles are coated with a layer of silica or not embedded within the active layer. In the first case, the improvement is attributed to a decrease of the exciton binding energy, which gives rise to enhanced free carrier generation and not enlarged light absorption.22 In the others, it is thought to be the result of multiple scattering23,24 and faster charge transfer at the TiO2–perovskite interface.22

Herein we present a detailed theoretical analysis of the effect of incorporating plasmonic gold nanoparticles on the optical absorption of organic–inorganic halide perovskite thin films. An increase in light collection in the spectral range where the material absorbs less, which corresponds to the spectral range at which the maximum number of solar photons impinges on the Earth surface and plasmonic effects take place, is observed. On this basis, we perform systematic studies to optimize solar light absorption of such perovskite thin films with embedded gold nanoparticles. With this aim, we analyze plasmonic near-field enhancement and scattering effects as a function of particle size, respectively. Both phenomena can be tuned to match the spectral range of interest, forcing more light to be absorbed and therefore improving the perovskite cell performance. A few initial attempts exploring this possibility have already been reported. Different experimental approaches were taken based on silica-coated gold spheres and gold–silver alloy particle clusters of irregular or planar shapes.22–24 In all cases, cell performance enhancements are observed, although the potential contribution of near-field enhancement effects is largely diminished or excluded, as the metal particles are coated with a layer of silica or not embedded within the active layer. In the first case, the improvement is attributed to a decrease of the exciton binding energy, which gives rise to enhanced free carrier generation and not enlarged light absorption.22 In the others, it is thought to be the result of multiple scattering23,24 and faster charge transfer at the TiO2–perovskite interface.22

concentration, particle location, and dimer formation, in order to account for all potential eventualities occurring during particle dispersion within the film and hence to determine design rules that maximize perovskite sunlight-harvesting properties.

2. RESULTS AND DISCUSSION

Three-dimensional (3D) finite-difference time-domain (FDTD) simulations are performed using the software FDTD Solutions from Numerical Solutions. A schematic of the systems here analyzed is shown in Figure 1, in which it can be seen that, in a first approximation, gold particles are considered to be dispersed in the middle of the perovskite film, at equal distances from both surfaces. We consider a plane wave propagating along the z-direction and impinging on a perovskite slab of a certain thickness, \( L_z \), containing a single gold nanoparticle (AuNP) of radius \( r \) centered at \((x, y, z) = (0, 0, 0) \) nm. (B) Schematics of the same system as that in panel (A) containing 2 AuNPs with a gap distance \( d \) in a double volume \( 2(L_x \times L_y \times L_z) \).

Figure 1. (A) Schematics of a unit cell with dimensions \( L_x \times L_y \times L_z \) of a glass-perovskite-SpiroOMeTAD system, each layer characterized with refractive indexes, \( n_\text{AuNP}(\omega) \), \( n_\text{P}(\omega) \), and \( n_\text{spiro}(\omega) \), respectively, containing a gold nanoparticle (AuNP) of radius \( r \) centered at \((x,y,z) = (0,0,0) \) nm. (B) Schematics of the same system as in panel (A) containing 2 AuNPs with a gap distance \( d \) in a double volume \( 2(L_x \times L_y \times L_z) \).

The refractive index of gold, \( n_\text{Au} \), propagating along the perovskite slab of a certain thickness, \( V_j \) volumes comprising gold nanoparticles. Our calculations are minimum mesh refinement, 0.2 nm, being used in cubic volumes comprising gold nanoparticles. Our calculations are further validated by comparing the results obtained for the total absorbance, estimated through \( A = 1 - R - T \), with those calculated numerically as \( A = A_P + A_\text{Au} \). We consider as a reference system a perovskite slab without AuNPs. Calculations of \( T_\text{Au} \), \( R_\text{tot} \) and \( A_\text{tot} \) realized by means of an analytical model based on refraction and transmission coefficients in plane-parallel systems are compared to numerical ones.

The solar absorptance enhancement of the perovskite film, \( \eta \), is determined by

\[
\eta = \frac{\int_{400}^{775} A_P(\lambda) \cdot \text{AM1.5} d\lambda}{\int_{400}^{775} A_\text{ref}(\lambda) \cdot \text{AM1.5} d\lambda}
\]

with AM1.5 being the normalized solar spectrum on the Earth’s surface with units [photons m\(^{-2}\) s\(^{-1}\) nm\(^{-1}\)]. With this definition, \( \eta > 1 \) implies an absorption enhancement; that is, the inclusion of AuNPs is beneficial for increasing the perovskite absorptance, and \( \eta < 1 \) indicates a detrimental effect of perovskite absorptance. In the calculations, the upper limit of the integral is taken to be 775 nm, as it has been demonstrated\(^{20,27} \) that perovskite absorptance at larger wavelengths does not lead to an increment of the external quantum efficiency (EQE). Therefore, we will limit our calculations to the integration range \([400, 775]\) nm. The set of geometrical parameters defining the perovskite volume \( V_P = L_x \times L_y \times L_z \) and sphere size (of radius \( r \)) is chosen according to experimental realization.\(^{20,27} \) In particular, we analyze the effect caused in the perovskite absorptance by embedding AuNPs as a function of: particle size, by changing the radius of the sphere; concentration, by modifying the surrounding perovskite volume; particle location inside the perovskite film; and dimer formation.

Figure 2 shows the perovskite solar absorptance enhancement, \( \eta \), as a function of NP radius, \( r \), for different concentrations, \( c \), different perovskite volumes \( L_x \times L_y \times L_z \) (as indicated in the figure), with (A) \( L_z = 200 \) nm and (B) \( L_z = 300 \) nm (Figure S2 in the Supporting Information shows results also for \( L_z = 100 \) nm systems). A general trend is observed in all cases: \( \eta \) increases with particle radius until it gets to a maximum. In particular, we find the largest enhancement for (A) AuNPs of 60 nm radius in a 200 \( \times \) 200 \( \times \) 200 nm\(^3\) perovskite volume and for (B) AuNPs of 90 nm radius in a 300 \( \times \) 300 \( \times \) 300 nm\(^3\) perovskite volume, which in both cases correspond to a filling fraction \( (V_\text{Au}/V_P) \) of 11.3% (corresponding filling fraction values of all the other cases here considered appear in Table S1 and Table S2 in the Supporting Information). At this stage, plasmonic coupling was prevented by considering long enough separation distances between neighboring gold particles. This was confirmed by simulations of field enhancement in systems of 2Lx \( \times \) 2Ly \( \times \) Lz containing two spheres separated a distance \((L_z - 2r)\) and \((L_z - 2r)\) along the corresponding directions. These systems would correspond to an equivalent system whose unit cell contains two unit cells of those considered for single spheres in a \( V_P \) volume. Modeled field enhancement and scattering effects, as well as the resulting absorption profiles, do not show any difference when compared to those observed for individual particles (Figure S3 in the Supporting Information). Hence, absorptance enhancements reported in Figure 2 can be considered as exclusively due to the presence of isolated spheres and not to array effects.

For the case of \( L_z = 300 \) nm, absorptance spectra of perovskite and gold are displayed in Figure 3A and 3B, respectively, for several NP radii. For comparison, we also show results obtained for the reference system, that is, the corresponding perovskite volume without any AuNP, which has been calculated with both FDTD and semianalytical models. As expected, the presence of a AuNP has a strong
the AuNP radius, \( L_x \), respectively, for a AuNP of the absorptance, \( \text{Absorptance} \), which increases in intensity with the sphere radius. Contour plasmon resonance at the lower amount of material, absorption of gold displays a case in which the perovskite slab absorbs less as a whole due to the spiro-OMeTAD system

\[ \text{Lx} = 200 \text{ nm}, \text{Lz} = 300 \text{ nm}, \text{and} \text{Lz} = 750 \text{ nm} \]

Figure 2. Perovskite solar absorption enhancement, \( \eta \), as a function of the AuNP radius, \( r \), in a glass–perovskite–SpiroOMeTAD system with \( L_x = L_z \). In panel (A) it is taken \( L_x = 200 \text{ nm} \) with \( L_z = 125 \text{ nm} \), (ii) 200 nm, (iii) 400 nm, and (iv) 600 nm, and in panel (B) \( L_z = 300 \text{ nm} \), taking \( L_x = 150 \text{ nm} \), (ii) 225 nm, (iii) 300 nm, (iv) 450 nm, and (v) 600 nm.

impact on the perovskite absorptance at long visible wavelengths. In panel (A) we observe that for all particle sizes absorption of light by the methylammonium lead iodide perovskite material decreases for wavelengths shorter than 500 nm as the particle radius increases. However, for \( \lambda \geq 500 \text{ nm} \), the perovskite absorptance increases for all sizes, a maximum being found for \( r = 90 \text{ nm} \). In panel (B), where only the light captured by the metal is considered, the shape of the absorptance curve demonstrates that the amount of light captured by the metal continuously increases with particle size at all wavelengths. Interestingly, competition between these two absorbing materials results in larger absorptance of gold only at very short and long wavelengths, hence the typical absorptance spectra of gold nanoparticles displaying plasmon resonances at \( \lambda \sim 550 \text{ nm} \) are not observed. This is a direct consequence of considering a strongly absorbing host medium surrounding the gold particle. However, in systems with less perovskite volume, competition between both materials is more balanced, and plasmonic resonances are apparent, as shown in Figure S4 in the Supporting Information for the case of \( L_z = 200 \text{ nm} \). In this case in which the perovskite slab absorbs less as a whole due to the lower amount of material, absorption of gold displays a plasmon resonance at \( \sim 600 \text{ nm} \) (the redshift arising due to the large real part of the refractive index of the external medium) which increases in intensity with the sphere radius. Contour plots in Figure 3 display (from top to bottom) the absorption profile at \( \lambda = 450 \text{ nm} \), \( \lambda = 600 \text{ nm} \), and \( \lambda = 750 \text{ nm} \) (maximum absorptance), respectively, for a AuNP of \( r = 90 \text{ nm} \). Analysis of the results at \( \lambda = 750 \text{ nm} \) reveals that a double contribution from near-field and scattering effects caused by the presence of plasmonic NPs in the perovskite film leads to reinforced light harvesting by the semiconductor. Contrarily, at those wavelengths for which the magnitude of scattering significantly overcomes that of near-field localization, the enhancement effect is substantially less noticeable or even absent. This consideration is of the utmost importance for the potential use of metal particles as light-harvesting enhancers in optoelectronic devices. Previous plasmonic particle-based approaches aiming at enhancing absorbance in perovskite solar cells usually consider silica-coated AuNPs,22,28 thus suppressing near optical field effects which, as we herein demonstrate, would have been essential to actually improve the productive absorption of the cell. Our results are also in agreement with previous works,22 in which no absorption enhancement was observed for particle sizes of \( r \approx 20 \text{ nm} \). The relative contribution of the two main effects affecting perovskite absorption, i.e., scattering and near-field localization, will vary significantly depending on the thickness of the slab considered. Moreover, results will also depend on particle size not only because of the volume it occupies at the expense of perovskite material but also for the reason that plasmonic near-field and light scattering effects have a strong dependence on the sphere diameter. All these considerations explain why maxima in Figure 2 are found at different particle sizes and concentrations as a function of slab thickness.

In what follows, we analyze the effect on the optical response of the slab of other features which are likely to be present in a dispersion of metal particles in a solid film, i.e., random particle location inside the perovskite slab and formation of dimers. The former is analyzed by considering different particle locations along the \( z \)-direction inside the slab. In Figure 4 we analyze in detail those cases for which we found maximum perovskite solar absorptance enhancement in Figure 2 (i.e, \( L_x = 200 \text{ nm} \) and \( r = 60 \text{ nm} \); and \( L_z = 300 \text{ nm} \) and \( r = 90 \text{ nm} \)). Panel (A) shows \( \eta \) as a function of particle position along the \( z \)-direction. Note that \( z = 0 \text{ nm} \) corresponds to a particle centered inside the slab, \( z < 0 \text{ nm} \) to systems in which the particle is located close to the glass substrate (that is, close to the illumination source), and \( z > 0 \text{ nm} \) to cases in which the particle is closer to the spiro-OMeTAD cover (far from the illumination source). Circles represent results for perovskite slabs of thickness \( L_z = 200 \text{ nm} \) with embedded gold spheres of \( r = 60 \text{ nm} \), while squares stand for \( L_z = 300 \text{ nm} \) containing spheres of \( r = 90 \text{ nm} \). Dashed lines display the expected average enhancement assuming a random metal particle distribution within the semiconductor film for \( L_z = 200 \text{ nm} \) and \( L_z = 300 \text{ nm} \), respectively. For \( L_z = 200 \text{ nm} \), a maximum enhancement is found for spheres located at \( z = +20 \text{ nm} \) (far from the source) leading to an enhancement of \( \sim 12\% \), while for thicker films the maximum enhancement (\( \sim 6\% \)) is obtained at \( z = -10 \text{ nm} \). This means that light must travel \( \sim 50 \text{ nm} \) within the perovskite film before it reaches the plasmonic scatterer in order to obtain an optimum performance. In addition, these results demonstrate that random distribution of particles along the \( z \)-direction will lead to average enhancements of \( \sim 7\% \) and \( 5\% \) for \( L_z = 200 \text{ nm} \) and \( L_z = 300 \text{ nm} \), respectively. Panel (B) displays absorptance spectra for a \( L_z = 300 \text{ nm} \) unit cell containing a AuNP of \( r = 90 \text{ nm} \) at different \( z \)-positions (\( z = -50 \text{ nm} \), \( z = -10 \text{ nm} \) and \( z = 50 \text{ nm} \)), whose comparison shows that the shape of the curve is very sensitive to this parameter. Contour plot insets correspond to absorption profiles at \( \lambda = 750 \text{ nm} \), the
wavelength at which maximum absorptance is found. From them, we can conclude that near-field effects dominate when the particle is close to the substrate, while scattering effects do when it is located near the spiro-OMeTAD cover. It is precisely the double contribution of plasmonic near-field and scattering effects found when the particle is closer to the center of the slab which leads to a maximum enhancement of the perovskite absorptance. Corresponding results for a $L_z = 200$ nm slab are shown in Figure S5 in the Supporting Information.

Although we are dealing with diluted solid suspensions of the metal particles in perovskite, formation of dimers during the actual preparation of the films cannot be entirely discarded. Thus, the analysis of the optical effects of this eventual outcome is also needed. For this reason, in Figure 5 we analyze the effect of dimer formation in perovskite films keeping the same concentration as before, i.e., considering 2 AuNPs in a double volume of $2(L_x \times L_y \times L_z)$ of perovskite. Panel (A) in Figure 5 displays perovskite solar absorptance enhancement as a function of the gap between the two particles, $d_g$, for perovskite volumes of $200 \times 400 \times 200$ nm$^3$ containing two spheres of $r = 60$ nm (circles) and of $300 \times 600 \times 300$ nm$^3$ containing two spheres of $r = 90$ nm (squares). Interestingly, formation of dimers is decidedly beneficial for thin perovskite slabs (in comparison to results for 1 AuNP), reaching a highest enhancement of almost 12% for gap distances of 20 nm, but the opposite effect is obtained for thicker films. For comparison, dashed and dotted lines represent the corresponding absorptance enhancement of a single sphere in half a volume ($200 \times 200 \times 200$ nm$^3$ and $300 \times 300 \times 300$ nm$^3$, respectively). In both cases, as $d_g$ approaches the separation distance of an equivalent system comprising two unit cells with one sphere per cell, the observed enhancement becomes that of a single sphere in half a volume, further confirming that array effects are excluded in our simulations. The different effect of dimers on the absorption of each slab thickness herein considered has its origin in the dissimilar response of both perovskite films at long wavelengths. This can be clearly seen in Figure 6, where we plot reflectance, transmittance, and absorptance for the case of the presence of dimers as well as that of single spheres in the two types of films. For the systems here considered and $d_g = 10$ nm we find that dimers scatter light mostly in the forward direction for the $L_z = 300$ nm case, which gives rise to a much higher transmittance in comparison with single spheres, while for the $L_z = 200$ nm case, the opposite behavior is found; i.e., higher transmission is found for single spheres in comparison to dimers. Corresponding field enhancement and absorption profiles at the wavelength at which perovskite absorptance is maximum are shown in Figures S6 and S7 in the Supporting Information, where it can be seen that the hot spot created in the interparticle gap occupies such a small volume that the effect on the perovskite absorptance is much less significant than that of scattering.

3. CONCLUSIONS

In conclusion, we have demonstrated, by means of numerical simulations, that the inclusion of plasmonic gold nanoparticles...
in thin organic—inorganic halide perovskite films leads to an enhancement of perovskite sunlight absorption that ranges between 6% and 12% for the set of film thicknesses considered. We find specific sets of realistic parameters in terms of particle size and concentration to maximize perovskite absorption. We demonstrate that absorption is maximized when plasmonic near-field and light scattering effects are adequately balanced. We have also analyzed the effect of having a random distribution of particles within the film, as well as the eventual formation of dimers, the conditions under which these events are beneficial or detrimental for perovskite absorption being found. Our results provide a guide to find the best optical design based on plasmonic effects for standard composition and thickness perovskite films and open the door to performance optimization of perovskite solar cells by the inclusion of gold nanoparticles within the active layer.
