Abstract

The kinetic of reduction of CuO to Cu₂O with N₂+O₂ mixtures and the oxidation of Cu₂O to CuO with O₂ of a Cu-based oxygen carrier for the CLOU process has been determined in a TGA. For kinetic determination, the O₂ concentrations were varied between 0 and 9 vol.% for reduction, and between 21 and 1.5 vol.% for oxidation reactions; temperature was varied between 1148 and 1273 K for the reduction and between 1123 and 1273 K for the oxidation. The oxygen carrier showed high reactivity
both in oxidation and reduction reactions. The nucleation and nuclei growth model with chemical reaction control properly described the evolution of solids conversion with time. The Langmuir-Hinshelwood model was able to describe the effect of oxygen concentration on reduction and oxidation rates. The reaction order was 0.5 for reduction and 1.2 for the oxidation. The kinetic constant activation energies were 270 kJ·mol⁻¹ for the reduction and 32 kJ·mol⁻¹ for the oxidation. The kinetic model was used to calculate the solids inventory needed in the fuel reactor for complete combustion of three different rank coals. It was possible to use a low oxygen carrier inventory in the fuel reactor (160 kg/MWth) to supply the oxygen required to full lignite combustion. However, to reach high CO₂ capture efficiencies (≥95%), oxygen carrier inventories in fuel reactor higher than 600 kg/MWth were needed with the lignite.

**Keywords:** CO₂ capture, chemical looping, CLOU, copper, kinetic.

1. **Introduction**

Chemical Looping with Oxygen Uncoupling (CLOU) was proposed by Mattisson et al. [1] as an efficient way to burn solid fuels with CO₂ capture avoiding the slow gasification step happening in the fuel reactor of a Chemical Looping Combustion (CLC) unit, which was usually required for converting carbon in char into gaseous compounds. CLOU process is based on CLC technology where the oxygen is transferred to the fuel by an oxygen carrier that circulates between two reactors; fuel and air reactors. CLOU process is based on the use of oxygen carrier materials which release gaseous oxygen and thereby allowing the solid fuel to burn with gas phase oxygen. These materials can be also regenerated at high temperatures in the air reactor.
CuO, Mn₂O₃ and Co₃O₄ have been identified as possible metal oxides with the property of release oxygen [1].

Fig. 1 shows a schematic diagram of a CLOU system. The fuel is physically mixed with the oxygen carrier in the fuel reactor. In the fuel reactor the fuel conversion is produced by different reactions. First the oxygen carrier releases oxygen according to:

\[
2 \text{Me}_x\text{O}_y \leftrightarrow 2 \text{Me}_x\text{O}_{y-1} + \text{O}_2 \quad (1)
\]

and the solid fuel begins to devolatilize producing a carbonaceous solid residue (char, mainly composed by carbon and ash) and volatile matter as gas product:

\[
\text{Solid fuel} \rightarrow \text{Volatile matter} + \text{Char (C)} \quad (2)
\]

Then, volatiles and char are burnt as in usual combustion with gaseous oxygen according to reactions (3) and (4):

\[
\text{Volatile matter} + \text{O}_2 \rightarrow \text{CO}_2 + \text{H}_2\text{O} \quad (3)
\]

\[
\text{Char (C)} + \text{O}_2 \rightarrow \text{CO}_2 + \text{ash} \quad (4)
\]

After steam condensation, a pure CO₂ stream is obtained from the fuel reactor. The reduced oxygen carrier is transported to the air reactor, where the oxygen carrier is regenerated to the initial oxidation stage with the oxygen of the air to be ready for a new cycle. Ideally, the exit stream of the air reactor contains only N₂ and unreacted O₂. The heat release over the fuel and air reactors is the same as for conventional combustion. Therefore CLOU process has a low energy penalty for CO₂ separation and low CO₂ capture costs are expected.

Up to date, several materials have been proposed to be used as oxygen carriers in the CLOU process. Cu-based [2-4] and Mn-based materials mixed with Ca, Mg, Cu, Ni, Fe or Si [5] have focused great attention. Adánez et al. [6] and Mattisson [7] summarize the
oxygen carrier developed for CLOU and the facilities where have been tested. However, the proof of the concept of CLOU process burning coal in a continuous unit has been only demonstrated with a Cu-based oxygen carrier [8]. This oxygen carrier, consists of 60 wt.% of CuO and 40 wt.% MgAl\(_2\)O\(_4\) prepared by spray drying [8, 9], and it was named as Cu60MgAl. The effect of the coal rank was also analysed [10] in the CLOU unit using one anthracite, two bituminous coals, a lignite with high sulphur content [11] and biomass [12]. Complete combustion using a solids inventory in the fuel reactor of 235 kg/MW\(_{th}\) was reached. In conjunction, values close to 100 % of carbon capture efficiency were obtained at 1233 K with reactive coals and biomass. In all cases, the oxygen carrier particles showed good behaviour, as reactivity was unchanged and agglomeration problems did not occur.

For the design of the air and fuel reactors of a CLOU unit it is necessary to know the kinetic of oxidation and reduction rates of the oxygen carrier together with the kinetic of coal combustion reactions in the operation window for CLOU process. Previous kinetic studies of Cu-based oxygen carriers were mainly carried out in the window of CLC conditions, in a range of temperature between 723 to 1073 K [13]. This temperature interval is lower than that needed in CLOU process. The main difference between the CLC and the CLOU process is that in CLOU process the oxygen carrier reduction is from CuO to Cu\(_2\)O. This reaction is favoured at high temperatures as can be seen with the equilibrium diagram in Fig. 2, being the oxygen concentration at equilibrium a function of the temperature as:

\[
C_{O_2,eq} = \frac{101325}{R_y T} K_{eq} = \frac{101325}{R_y T} \exp \left(22 - 2.993 \times 10^4 T^{-1} - 1.048 \times 10^6 T^{-2}\right)
\]  

(5)

Thermodynamic equilibrium set the temperatures and oxygen concentrations suitable for the CLOU process. So, the oxygen concentration at equilibrium conditions must be
high enough to allow the $O_2$ release in the fuel reactor and also the combustion of the fuel at the fuel reactor temperature. Moreover, the oxygen carrier must be able to oxidize by oxygen in the air reactor, but the oxygen concentration should be as low as possible in order to maximize the oxygen utilization. For example, with Cu-based materials the temperatures should be between 1173 to 1223 K in both reactors [8, 10] corresponding to oxygen concentration values at equilibrium conditions of 1.4 and 4.2 vol.%, respectively.

At high temperature and in an atmosphere with oxygen concentration lower than the equilibrium, the CuO is reduced to Cu$_2$O generating gaseous oxygen. This fact makes that the oxygen concentration at equilibrium a thermodynamic restriction in the reduction reaction affecting to the reduction rate. Thus, the oxygen concentration must be in a range from 0 to the oxygen equilibrium concentration in the fuel reactor. Furthermore, in the CLOU process the reduction stops at Cu$_2$O instead of at Cu, allowing to work at higher temperatures in CLOU than in CLC without the risk of oxygen carrier agglomeration by melting ($T_{fusion} = 1508$ K for Cu$_2$O and 1357 K for Cu). Oxidation would be carried out at the air reactor in an oxygen concentration range between 21 vol.% $O_2$ and the oxygen equilibrium concentration.

There are some studies on the reduction, or oxygen uncoupling, and oxidation kinetic for Cu-based materials. Table 1 shows a resume of the main kinetic parameters studied in the literature for CLOU or similar processes for the reduction and oxidation reactions; also the oxygen carrier (CuO content, support and preparation method) and the model used were shown. Most of the works were focused on the evaluation of the effect of temperature on reaction rate, thus calculating the activation energy of the process. Two types of reaction rate equations have been used to represent the CuO oxygen uncoupling and Cu$_2$O oxidation reaction for the CLOU process [14, 15]:
\[ (-r_{\text{red}})_{OC} = k_1 \cdot f(X) \]  \hspace{1cm} (6)

\[ (-r_{\text{red}})_{OC} = k_2 \left( C_{O_2, eq} - C_{O_2} \right)^n \cdot f(X) \]  \hspace{1cm} (7)

It can be seen that in Eq. (6) the reduction rate only depends on temperature (included in the kinetic constant) and on oxygen carrier conversion, \( f(X) \). On the other hand, reaction rate also depends on the oxygen concentration in Eq. (7). Different values for the activation energy were obtained either Eq. (6) or Eq. (7) was considered. Thus, a global activation energy \( (E_1) \) for \( k_1 \) in Eq. (6) was calculated when the effect of temperature on both the chemical reaction barrier and the thermodynamic barrier was considered. But the kinetic activation energy was calculated for \( k_2 \) in Eq. (7), which separates the thermodynamic barrier \( (E_{th}) \) from the chemical reaction barrier \( (E_2) \).

Eqs. (6) and (7) are also valid for the oxidation reaction considering the oxidation reaction rate, \( (r_{\text{ox}})_{OC} \), can be calculated by \( (r_{\text{ox}})_{OC} = (-1)^n (-r_{\text{red}})_{OC} \). If the reaction order is \( n' \approx 1 \), the global activation energy for \( k_1 \) can be calculated approximately as

\[ E_1 \approx E_2 + E_{th} \], being \( E_{th} = 255 \cdot 10^3 \text{ J/mol} \) in Eq. (5). It can be seen that different values for the activation energy were obtained either Eq. (6) or Eq. (7) was considered. Thus, a global activation energy \( (E_1) \) for \( k_1 \) in Eq. (6) was calculated when the effect of temperature on both the chemical reaction barrier and the thermodynamic barrier was considered jointly. But kinetic activation energy due to chemical reaction barrier \( (E_2) \) calculated for \( k_2 \) in Eq. (7) was decoupled from the thermodynamic barrier \( (E_{th}) \) considered by the oxygen concentration at equilibrium condition.

Respect to the reduction, Chadda et al. [16] did an analysis of the copper oxide capacity of storage chemical energy for a process similar to CLOU. They studied the same reaction of decomposition of CuO in a range of temperatures from 1033 to 1183 K. In this work, a global activation energy of 313 kJ/mol for the decomposition reaction was
found. Eyring et al. [17] studied the reduction kinetic for a pure CuO oxygen carrier in a TGA. They obtained a value of the activation energy for the reduction of 327 kJ/mol using an empirical first order reaction, developed for their purposes of modelling.

Similar results were found by Clayton and Whitty [15]. They determined in a TGA the reduction kinetic rate for two different Cu-based oxygen carriers: 50 wt.% CuO/TiO$_2$ and 45 wt.% CuO/ZrO$_2$, prepared by mechanical mixing and freeze granulation respectively. The global activation energies determined were 284 kJ/mol (CuO/TiO$_2$) and 264 kJ/mol (CuO/ZrO$_2$). These values were slightly lower than the values obtained by Chadda et al. [16, 17] or Eyring et al. [16, 17], but they were still high when compared to results from others.

Song et al. [18] studied in a TGA the kinetic of a Cu-based oxygen carrier with 18 wt.% of CuO supported on SiO$_2$, prepared by impregnation for the Chemical Looping Air Separation (CLAS) process, which uses the same oxygen uncoupling property of some metal oxides to separate oxygen from air. They considered the best model to be the Avramie-Erofeev nucleation model ($N=2$) with two different zones as a function of the temperature range, for temperatures between 1073 to 1173 K the global activation energy was 315 kJ/mol and in the range 1173-1248 K they obtained a value of 176 kJ/mol. This suggests that the temperature could affect to the calculated activation energy. This behaviour was also found for a CuO (50 wt.%) oxygen carrier with TiO$_2$ as supporting material [19]. Thus, an activation energy of 284 kJ/mol was found in the 1073-1173 K temperature interval [15], but it was lower (180 kJ/mol) if the range of temperature was increased to 1173-1273 K [19]. The same authors reported average activation energy for a Cu-based material supported on ZrO$_2$ of 147 kJ/mol in the temperature interval of 1073-1273 K [19], but also a decrease in the activation energy with temperature could be seen from the Arrhenius plot they showed. Similarly,
Peterson et al. [20] prepared Cu-based oxygen carrier materials by impregnation on SiC. They obtained a value of global activation energy for an oxygen carrier with 42 wt.% of CuO in the middle interval (220 kJ/mol) when the temperature was varied from 1123 to 1223 K.

However, other authors have determined activation energy values in the lower range at the low temperature interval, and even high activation energy values in the upper temperature interval; see Table 1. The reasons for obtaining high or low activation energy values are not clear. Thus, comparing results obtained with similar materials, e.g. Cu-based oxygen carriers with copper content in the range 40-60 wt.% and using ZrO$_2$ as inert material, activation energy values ranged from 147 to 281 kJ/mol [14, 15, 19, 21]. Nevertheless, the global activation energy was calculated to be in the lower range in most of the works. Arjmand et al. [22] studied the kinetic in a batch fluidized bed reactor of a Cu-based oxygen carrier (40 wt.% of CuO and 60 wt.% MgAl$_2$O$_4$) prepared by freeze granulation. They obtained a value of the global activation energy of 139 kJ/mol using the Avrami-Erofeev model ($N=2$). Wang et al. [21] studied the reduction reaction kinetic using three Cu-based oxygen carrier with 60 wt.% of CuO and 40 wt.% of three different supports (ZrO$_2$, TiO$_2$ and SiO$_2$) for CLAS process. The oxygen carriers were prepared by mechanical mixing and tested in a TGA. They obtained a value of the global activation energy of 153 kJ/mol (CuO/ZrO$_2$), 155 kJ/mol (CuO/TiO$_2$) and 145 kJ/mol (CuO/SiO$_2$) and they proposed to use the Avrami-Erofeev model ($N=3$). Similar global activation energy value of 170 kJ/mol was found for a CuO/SiO$_2$ material by Whitty and Clayton [19].

Also, the equipment used for reactivity investigation seems to be of low relevance. For example, Whitty and Clayton [19] studied the effect of the temperature in the reduction of three Cu-based oxygen carriers: 20 wt.% CuO/SiO$_2$, 50 wt.%CuO/TiO$_2$ and 55 wt.%
CuO/ZrO$_2$, prepared by incipient wetness, mechanical mixing and freeze granulation, respectively. They tested the oxygen carriers in 3 different reactor types (TGA, fluidized bed reactor and fixed bed reactor) obtaining similar results with the three facilities.

If the kinetic and the thermodynamically barriers were separated, lower values of the kinetic activation energies were determined, as result of including the temperature effect on the thermodynamic barrier; see Eq. (7). Thus, the following values for the kinetic activation energy has been reported: 58 kJ/mol [15] for CuO/TiO$_2$, and 67 kJ/mol [15] or 20 kJ/mol [14] for CuO/ZrO$_2$.

Moreover, Clayton and Whitty [15] studied the reaction order with respect to the oxygen partial pressure; they observed that the reaction rate decreased as the driving force decreased, and with an unexpected great decrease when the oxygen partial pressure was near the equilibrium pressure. However, only experiments far from the O$_2$ equilibrium were considered to obtain a reaction order of 1. Sahir et al. [14] calculated the reaction order with respect to CuO and obtained a value of 0.

Respect to the oxidation rate, Chadda et al. [16] did an analysis of the capacity of chemical energy storage with copper materials during the oxidation of Cu$_2$O in a range of temperatures form 673-773 K. In this work, an activation energy value of 76.5 kJ/mol for oxidation was found. Zhu et al. [23] reviewed the oxidation rate of a Cu plate of very high purity in a high range of temperatures from 623K to 1323 K, for metallurgic purposes. They conclude that at high temperatures (> 1173 K, typical for CLOU operation) lattice diffusion controlled the copper oxidation, and the activation energy were between 173 to 98 kJ/mol as a function of the formation of a double- or single-layer respectively.

Also, some works have studied the kinetic behaviour during oxidation of Cu$_2$O for CLC. Peterson et al. [20] observed that the oxidation rate decreased somewhat when the
temperature increases, due to the decrease of the driving force, i.e. the difference
\( (C_{O_2} - C_{O_2,eq}) \). Whitty and Clayton [19] obtained an activation energy of 202 kJ/mol in the temperature interval of 1123-1273 K when the driving force was maintained constant, which suggests that the activation energy of the thermodynamic barrier is some higher than the kinetic activation energy. The activation energy calculated by Whitty and Clayton [19] was higher than the values obtained by Zhu et al. [23]. They blame this higher apparent activation energy due to the presence of defects in the material that inhibits the lateral grown of the CuO grains [23]. Finally, Song et al. [18] studied the oxidation of different Cu-based oxygen carriers prepared by dry impregnation for CLAS (18, 29 and 48 wt.% of CuO). They evaluated the effect of the temperature in the oxidation rate, obtaining two different zones respect to the activation energy: in the range of 1073-1173 K the activation energy is positive with a value of 3 kJ/mol, but at temperatures in the 1173-1248 K interval the value of the activation energy is -43 kJ/mol. They considered that the negative value is due to both the thermodynamic barriers of the Cu\(_2\)O oxidation and the high diffusional barrier caused by the sintering effects at high temperatures [18, 23]. Also, they considered that the best model to describe the oxidation rate is a Boundary reaction model. Using this model they analysed the effect of the oxygen partial pressure during the oxidation and they obtained a reaction order for the oxygen partial pressure of 0.5. However, they use O\(_2\) partial pressures far from the equilibrium partial pressure. Whitty and Clayton, [19] observed the oxidation rate decreased when the O\(_2\) concentration decreased, but lower than they expected when the O\(_2\) concentration approached to equilibrium. Chuang et al. [24] studied the oxidation kinetic with a CuO/Al\(_2\)O\(_3\) oxygen carrier prepared by co-precipitation in a fluidized bed reactor. They studied the reaction order for the oxygen concentration and they observed that the order varied with the O\(_2\) concentration. They
explain that this behaviour is typical when the reaction rate is controlled by a Langmuir-Hinshelwood mechanism.

As a conclusion, very disperse values for the kinetic data of Cu-based materials for CLOU were found. These data were found from studies analyzing only temperature dependency or oxygen concentration but far away from equilibrium conditions. For these reasons, it is necessary to analyze the effect of temperature and oxygen concentration on oxidation and reduction reactions in a broad range of operation values.

The aim of this work was to determine the kinetic of reduction in N₂-O₂ mixtures and oxidation reactions with O₂ of a Cu-based oxygen carrier (Cu₆₀MgAl) prepared by spray drying in the range of operation of the CLOU process. This material has been previously used to successfully prove the CLOU concept with several solid fuels. The effect of O₂ concentration and temperature was investigated both for oxygen uncoupling and oxidation processes in TGA. The kinetic parameters obtained were used to determine the solids inventories needed in a CLOU system working with this Cu-based oxygen carrier. Kinetic parameters obtained in this work can be implemented in a design and optimization tool for CLOU process.

2. Experimental

2.1. The Cu-based oxygen carrier

The oxygen carrier used in this work was a Cu-based material prepared by spray drying. Oxygen carrier particles were manufactured by VITO (Flemish Institute for Technological Research, Belgium) using CuO (Panreac, PRS) and MgAl₂O₄ spinel (Baikowski, S30CR) as raw materials. The particles were calcined 24 h at 1373 K. The CuO content was 60 wt.%. The particle size of the oxygen carrier was +0.1-0.3 mm.
From now on, the oxygen carrier is named as Cu60MgAl. Table 2 shows the main properties of this material, which were presented in previous works [2, 8-11, 25].

The oxygen transport capacity, $R_{OC}$, is an important characteristic of the oxygen carrier. $R_{OC}$ has relevance on the solids circulation rate and solids inventory in a CLC unit [26]. $R_{OC}$ was calculated in TGA in nitrogen atmosphere as $R_{OC} = (m_{Ox} - m_{Red})/m_{Ox}$, being $m_{Ox}$ the mass of fully oxidized particles and $m_{Red}$ in the reduced form after oxygen uncoupling, i.e. when all CuO has been reduced to Cu$_2$O.

Preliminary results showed that this material has adequate values of reactivity and oxygen transport capacity in fluidized-bed conditions [9, 25]. High combustion rates with complete combustion to CO$_2$ and H$_2$O were obtained with this material using a low solids inventory in the fuel reactor of a CLOU unit burning different types of coal and biomass [8, 10].

2.2. Experimental set-up

Multicycle tests to analyze the reactivity of the oxygen carrier during successive reduction-oxidation cycles were carried out in a TGA CI Electronics type described elsewhere [2]. The desired mass of oxygen carrier was loaded in a platinum wired mesh basket (14 mm diameter and 8 mm height). Initially, to establish whether thermodynamic limitations, external film mass transfer and/or inter-particle diffusion were affecting the reaction rate, the sample weight and the gas flow rate were varied in the range of 40 to 100 mg and from 10–40 NL/h. The composition of the gas flow were pure N$_2$ for the reduction and air for the oxidation. It was found that using a sample mass lower than 70 mg, the control of gas diffusion inside the particles was avoided. On the other hand, it was found that the reaction rate was not controlled by interparticle
diffusion or diffusion through the gas film around the particle when N₂ flow was higher than 20 NL/h. Therefore, gas flow rate of 25 NL/h and 50 mg of solids were used to reduce mass transfer resistance around the solid sample. As it was shown by Gayán et al., [2], the use of these conditions ensured the minimization of external film mass transfer and/or inter-particle diffusion effects in the TGA. Moreover, the temperature in the reaction zone can greatly affect to the reaction rate and it was carefully checked. Deviations lower than 2 K were found in all cases during the reaction period. Moreover, previous studies showed that oxygen carrier particles can be considered isothermal during reduction or oxidation [27].

The sample was heated to the set operating temperature in air atmosphere. After stabilization, the experiment started by exposing the oxygen carrier to alternating reducing and oxidizing conditions. The experiments were carried out at temperatures between 1123-1273 K for the reduction and oxidation reactions. These temperatures were selected as a function of the thermodynamic equilibrium of the CuO/Cu₂O system, as shown in Fig. 2, being this temperature interval of interest for fuel and air reactors in CLOU process [8, 10].

The reaction gas mixture was composed by O₂ and N₂ in different relations for the reduction and oxidation. Table 3 summarizes both temperature and oxygen concentrations used for reduction and oxidation tests. For the reduction, the amount of O₂ varied from 0 to 9 vol.%. In the case of the oxidation, the oxidation reaction was carried out after reducing the oxygen carrier in N₂ at 1273 K and the concentration of O₂ was varied between 21 to 2.5 vol.%. These conditions allowed studying the effect of the oxygen concentration far away and near the equilibrium conditions. Three cycles of reduction and oxidation were carried out for each experiment. In all cases, reaction rate
was stable during cycles. Conversion vs. time curves showed in this work corresponded to the third cycle of each experimental condition.

2.3. Data evaluation

The release of O\(_2\) (reduction of CuO) and the oxidation of Cu\(_2\)O is given by the following equilibrium:

\[
4\text{CuO} \rightleftharpoons 2\text{Cu}_2\text{O} + \text{O}_2
\]  

(8)

The oxygen carrier conversion was calculated for the reduction and oxidation as:

\[
X_{\text{Red}} = \frac{m_{\text{ox}} - m}{m_{\text{ox}} - m_{\text{Red}}} \quad (9)
\]

\[
X_{\text{Ox}} = 1 - \frac{m_{\text{ox}} - m}{m_{\text{ox}} - m_{\text{Red}}} \quad (10)
\]

being \(m\) the mass of sample at each time, \(m_{\text{ox}}\) is the mass of the sample fully oxidized and \(m_{\text{Red}}\) is the mass of the sample in the reduced form, i.e. when copper was in the Cu\(_2\)O form.

The reaction rate for both, reduction and oxidation, are calculated from TGA conversion data using the following expressions:

\[
(-r_{\text{Red}})_{\text{OC}} = R_{\text{OC}} \frac{dX_{\text{Red}}}{dt} \quad (11)
\]

\[
(r_{\text{Ox}})_{\text{OC}} = R_{\text{OC}} \frac{dX_{\text{Ox}}}{dt} \quad (12)
\]
3. Results

To obtain the reduction and oxidation kinetic, TGA tests were carried out varying the temperature and the oxygen concentration in a wide range of values, from far away of the equilibrium to values near the equilibrium.

3.1. TGA results for oxygen uncoupling (CuO to Cu$_2$O)

Fig. 3(a) shows conversion versus time curves for the Cu60MgAl oxygen carrier for different temperatures between 1148 to 1273 K, using pure N$_2$ in the reacting environment during the reduction, and a O$_2$ concentration equal to 0 vol.%. It can be seen that when the temperature increases, the reduction rate increases. Considering reduction rate given by Eq. (7), reaction rate increased with temperature because the increase of the kinetic constant and the oxygen driving force. Often, this effect is expressed by means of the difference between the oxygen concentration at equilibrium and the oxygen concentration in the system surrounding of the particles, i.e. 

\[ \left( C_{O_2,eq} - C_{O_2} \right) \]. Thus, the reduction rate depends on the O$_2$ concentration at the external surface of the particles and the O$_2$ concentration at equilibrium conditions, which also increases with temperature following Eq. (5).

Fig. 3(b) shows the conversion versus time curves obtained for the Cu60MgAl oxygen carrier for three different temperatures during the reduction, using a concentration of 1.5 vol.% of O$_2$ in N$_2$. It can be observed that these curves were slower than the curves at the same temperature without oxygen. This figure confirms that the reaction rate decreases when the driving force decreases due to the approaching of the O$_2$ concentration to the equilibrium concentration.

To analyse the effect of the oxygen concentration on the reduction rate, Fig. 4 shows conversion vs. time curves for oxygen reduction reaction of Cu60MgAl obtained for O$_2$
concentration values from 0 to 9 vol.% at 1273 K. This interval of O₂ concentration has been chosen due to the maximum O₂ concentration is limited by the O₂ concentration at equilibrium condition, e.g. 12 vol.% at 1273 K; so O₂ concentration during TGA test was lower than equilibrium concentration. The oxygen uncoupling rate decreases when the O₂ concentration increases due to the decrease in the driving force of the reaction. This decrease was more pronounced when the O₂ partial pressure was close to the equilibrium concentration. Moreover, it was not possible to detect a change in the mass of the sample in the TGA when the O₂ concentration was very close to the equilibrium (y₀ > 9 vol.%), because the reaction rate was very slow. This behaviour was also described by Clayton and Whitty [15], during the reduction when the driving force was close to zero.

3.2. TGA results for oxidation (Cu₂O to CuO)

Fig. 5(a) shows conversion vs. time curves obtained for oxidation of Cu₂O in reduced oxygen carrier samples at oxygen concentration values from 21 to 2.5 vol.% at 1173 K. The oxidation rate was fast when the oxygen concentration was much higher than the oxygen concentration at equilibrium conditions, but quickly decreases as the oxygen concentration approach to the equilibrium concentration. This effect also was observed by Whitty and Clayton [19] when the driving force of the oxidation reaction decreased. Fig. 5(b) shows conversion vs. times curves for the Cu60MgAl oxygen carrier for different temperatures between 1123 to 1273 K, using air as reactant gas. It can be seen that reaction rate decreased when the temperature increased, being the slowest the reaction at 1273 K, due to the decrease in the driving force of the reaction, which in this case is \( (C_{O_2} - C_{O_2,eq}) \). So, the oxygen driving force decreases as temperature increases due to \( C_{O_2,eq} \) increases with temperature. This behaviour was observed by Zhu et al. [23]
for the oxidation of pure copper, but with an additional reason to justify their results. They considered that the decrease in the oxidation rate with the temperature was due to the high diffusional barrier caused by the sintering effects at high temperatures, additionally to the thermodynamic barriers of the Cu$_2$O oxidation.

### 3.3. Kinetic information from conversion curves

With the different conversion vs. time curves obtained for the reduction and oxidation as a function of the temperature, it was possible to obtain the evolution of the reaction rate with solids conversion. The maximum values calculated for every curve was used to obtain the global activation energy for the reduction and oxidation rates from the Arrhenius plot; see Fig. 6. The calculated value of the global activation energy for the reduction reaction was 245 kJ/mol, which is in the same order than the values obtained by Sahir et al. [14] with a oxygen carrier 40 wt.% of CuO supported by ZrO$_2$ (281 kJ/mol), Peterson et al. [20] for a material with 42 wt.% CuO being SiC the support (220 kJ/mol), and Clayton and Whitty [15] for two Cu-based oxygen carriers with a 50 wt.% and 45 wt.% of CuO supported on TiO$_2$ (284 kJ/mol) and ZrO$_2$ (264 kJ/mol), respectively.

Following the same procedure, a value for the apparent activation energy of -37 kJ/mol was calculated for the oxidation reaction; see Fig. 6. This value is similar to the value obtained by Song et al. [18], who calculated a negative apparent activation energy of -43 kJ/mol in the range of temperature 1173-1248 K.

Moreover, from the conversion vs. time curves obtained at different oxygen concentrations, some information can be extracted about the reaction order with respect to the oxygen concentration considering Eq. (7). Fig. 7(a) shows the curve of the
$\ln(-r_{\text{red}})_{OC}$ as a function of the $\ln(C_{O_2,eq} - C_{O_2})$. Considering Eq. (7), the reaction order corresponded to the slope in Fig. 7(a). However, a constant slope cannot be calculated, which means that the reaction order changed with the oxygen concentration.

Considering results showed in Fig. 7(a), an expression for the effect of oxygen concentration such Eq. (7), i.e. $f(C_g) = \left(C_{O_2,eq} - C_{O_2}\right)^{n'}$, seemed to be not valid when a wide range of values of oxygen concentration was considered.

Similarly to the analysis of the reduction period, Fig. 7(b) shows the reaction rate as a function of the oxygen concentration. In this case, a constant slope can be calculated. Therefore, the reaction order does not depend on the oxygen concentration, and it was found a $n'$ value of 1. However, Chuang et al. [24] observed a change in the reaction order with the oxygen concentration for the oxidation of a Cu-based oxygen carrier, similarly to what we found for the reduction in this work. Chuang et al. [24] suggested that this behaviour can be explained by using a Langmuir-Hinshelwood mechanism for the Cu$_2$O oxidation.

Subsequently, the Langmuir-Hinshelwood mechanism was considered in this work to determine the kinetic for the reduction reaction. To be consequent with the reduction, also a Langmuir-Hinshelwood mechanistic model was used to describe the oxidation in the CLOU process. In this way, results obtained here and found by Chuang et al. [24] could be adequately predicted for the oxidation reaction.
3.4. Kinetic model

3.4.1. Reduction from CuO to Cu₂O

A surface reaction model using a Langmuir-Hinshelwood mechanism is here proposed to describe the CuO reduction reaction to Cu₂O with O₂ generation. The CuO in the surface decomposes into Cu₂O by reaction with a active sites giving oxygen adsorbed in the surface. Then oxygen is desorbed to O₂, regenerating the a active sites in the surface [28]. Applying this model to the decomposition of CuO, following equations are obtained:

1. Chemical decomposition of CuO into Cu₂O and adsorbed O₂, which is a dynamic equilibrium between forward and backward reaction:

\[ 4CuO + aL \overset{k_f}{\underset{k_b}{\rightleftharpoons}} 2Cu_2O + aL(O_2), \quad K_1 = \frac{k_f}{k_b} \]  \hspace{1cm} (13)

2. Desorption of adsorbed O₂:

\[ aL(O_2) \overset{k_n}{\underset{k_r}{\rightarrow}} aL + O_2, \quad K_2 = \frac{k_n}{k_r} \]  \hspace{1cm} (14)

aL(O₂) is one molecule of O₂ chemisorbed on a active sites L.

When the reaction is controlled by chemical decomposition, Eq. (13), the reaction rate is given by:

\[ \frac{dX_{Red}}{dt} = k_{Red}S_{CuO} (1 - \theta) \left[ 1 - \frac{C_{O_2}}{C_{O_2,eq}} \right] f(X_{Red}) \]  \hspace{1cm} (15)

where \( \theta \) is the fraction of actives sites occupied by O₂. At these conditions, it is possible to use different adsorption isotherms to obtain the value of \( \theta \). García-Labiano et al. [29] selected the Freundlich isotherm to properly describe the CaCO₃ calcination [29]. In this case, the use of the Freundlich isotherm successfully described the effect of CO₂.
concentration on the CaCO₃ calcination rate, which showed an effect of the CO₂ concentration on the reaction rate similar to the O₂ effect observed for the reduction reaction in this work. Thus, the Freundlich isotherm was selected in this work to describe the fraction of occupied active sites, i.e. θ parameter, which was calculated by the following equation:

$$\theta = cC_{O_2}^{-1/n}$$  \hspace{1cm} (16)

$$c = c_0e^{-E_r/R_T}$$  \hspace{1cm} (17)

Combining Eq. 15 and Eq. 16, the reaction rate expression is as follow:

$$\frac{dX_{\text{red}}}{dt} = k_{\text{red}}f(X_{\text{red}})S_{\text{CuO}}\left(1 - cC_{O_2}^{-1/n}\right)\left(1 - \frac{C_{O_2}}{C_{O_2,eq}}\right)$$  \hspace{1cm} (18)

Different models have been used for the $f(X_{\text{red}})$ function in Eq. (18), including nucleation mechanism [18, 21, 22] or first order chemical reaction [14, 16]. The Langmuir-Hinshelwood mechanism is a surface reaction model widely used for gas-solid catalytic reactions. Due to this surface reaction, in this work it was proposed using the nucleation model to describe the conversion dependency in the reaction at the grain surface of the oxygen carrier particles.

The Avrami-Erofeev [30] equation corresponding to the nucleation mechanism is the following:

$$f(X_{\text{red}}) = N^{-1}(1 - X_{\text{red}})[-\ln(1 - X_{\text{red}})]^{1-N}$$  \hspace{1cm} (19)

The final expression for the reduction reaction rate, including Eq. (19) for the conversion function, is the following:

$$\frac{dX_{\text{red}}}{dt} = k_{\text{red}}S_{\text{CuO}}\left(1 - cC_{O_2}^{-1/n}\right)\left(1 - \frac{C_{O_2}}{C_{O_2,eq}}\right)^{N^{-1}(1 - X_{\text{red}})[-\ln(1 - X_{\text{red}})]^{1-N}}$$  \hspace{1cm} (20)
By integration of Eq. (20), the following equation was obtained to calculate the conversion evolution with time:

$$
\left[ -\ln \left(1 - X_{\text{Red}} \right) \right]^N = k_{\text{Red}}^s S_{\text{CuO}} \left(1 - c C_{\text{O}_2}^{\nu_n} \right) \left(1 - \frac{C_{\text{O}_2}}{C_{\text{O}_2,\text{eq}}} \right) t
$$

(21)

An effective kinetic constant was defined as:

$$
k_{\text{Red}}' = k_{\text{Red}}^s S_{\text{CuO}} = k_{\text{Red},0} e^{-E_{\text{Red}}/R_g T}
$$

(22)

The kinetic model has four parameters at each temperature ($N$, $n$, $k_{\text{Red}}'$ and $c$), which must be calculated as a function of temperature. The value of $N$ represent the type of nucleation and the nuclei growth in the model, which value is usually fixed between 1/4 and 3. To calculate the best value of $N$, Fig. 8(a) shows a plot of $\left[ -\ln \left(1 - X_{\text{Red}} \right) \right]^N$ vs. time for different values of $N$ using conversion vs. time data of Fig. 3. Linear regression of each data shows the fit to a linear plot. Table 4 shows the values of the correlation coefficients for the different values of $N$. Best fitting to a linear curve correspond to $N$ equal to 3/4. This procedure has been done for the conversion data at each temperature and oxygen concentration analysed in this work, obtaining the same result of $N$ for all of them.

To determine the values of the chemical rate constant, $k_{\text{Red}}'$, and its variation with temperature, experiments carried out at different temperatures between 1148 to 1273 K with an atmosphere of 100 vol.% N$_2$ were considered. In this case, Eq. (21) is simplified to $\left[ -\ln \left(1 - X_{\text{Red}} \right) \right]^N = k_{\text{Red}}' t$. Considering an Arrhenius dependence of $k_{\text{Red}}'$, Fig. 9 shows the Arrhenius plot for the reduction reaction, and Table 5 shows the kinetic parameters for pre-exponential factor and activation energies obtained. The value of the activation energy was 270 kJ mol$^{-1}$. This value can not be compared with activation energy data
from the literature because the kinetic model here proposed has not been previously used. The activation energy determined depends on the number of temperature dependent parameters considered in the kinetic model. Thus, the global activation energy was calculated with only \( k_1 \) as function of temperature, see Eq. (6). Kinetic activation energy was calculated with two temperature dependent parameters, i.e. \( k_2 \) and \( C_{O_{eq}} \), see Eq. (7); in this work the activation energy had an additional parameter, \( c \), affected by temperature in the kinetic model proposed.

Parameters \( n \) and \( c \) in Eq. (21) were calculated considering the effect of the partial pressure of oxygen in the oxygen carrier reduction rate. After integration and some algebra with Eq. (20), the following expression was obtained:

\[
Y_x = \ln \left[ 1 - \frac{1}{k_{red} \left( 1 - \frac{C_{O_x}}{C_{O_{eq}}} \right)^{N^{-1} \left( 1 - X_{red} \right) \ln (1 - X_{red})^{-1}}} \right] = \ln(c) + \frac{1}{n} \ln(C_{O_x}) \tag{23}
\]

Reaction rate was calculated for \( X_{red} = 0.2 \) due to a maximum conversion rate at this \( X_{red} \) value is reached using this model with \( N = 3/4 \).

Plotting the left handside of Eq. (23), \( Y_R \), parameters \( c \) and \( n \) can be calculated from the origin and slope of the plot \( Y_R \) vs. \( \ln(C_{O_x}) \); see Fig. 10(a). From this, a value of 0.5 for \( n \) (see Table 5) for all temperatures was found. Different values of \( c \) were obtained at each temperature. Considering an Arrhenius dependence of \( c \), Fig. 9 shows the Arrhenius plot for the reduction reaction, and Table 5 shows the parameters for pre-exponential factor and activation energies obtained for \( c \) from Eq. (17). It can be seen that the value of the activation energy for the parameter \( c \) is negative (-240 kJ/mol), as it corresponds to an adsorption process.
The Freundlinch isotherm and the nucleation model were used to fit experimental conversion vs. time data for different O₂ concentrations and temperatures. Fig. 3 (a) shows experimental and theoretical conversion vs. time curves at different temperatures and 0 vol.% of O₂. Fig. 3(b) shows experimental and theoretical lines of conversion vs time for three different temperatures (1223, 1248 and 1273 K) during reduction period using an O₂ concentration of 1.5%. Fig. 4 shows a comparison between experimental data and model predictions for different O₂ concentrations at constant temperature. It can be seen a very good fit between experimental and theoretical curves with the proposed kinetic model for all the temperature and oxygen concentration intervals, including reaction conditions with O₂ concentration far away and close to the equilibrium. This result indicates that the Freundlinch isotherm with a nucleation model with \( N = 3/4 \) was valid to describe the decomposition of the CuO in a broad range of O₂ concentrations. Thus, the kinetic model here proposed properly predicted the reaction rates when the O₂ concentrations was close to the equilibrium, where previous literature models had failed [15]. This condition is required in the fuel reactor of a CLOU unit to avoid unconverted compounds exiting the fuel reactor [8, 25].

### 3.4.2. Oxidation from Cu₂O to CuO

Also, a Langmuir-Hinshelwood mechanistic model has been used to describe the chemical reaction of Cu₂O oxidation in the CLOU process.

1. **Adsorption of O₂ over the surface of Cu₂O:**

   \[
   O_2 + aL \overset{K_i}{\longrightarrow} aL(O_2) \quad K_i = \frac{k_i}{k_p}
   \]  \hspace{1cm} (24)

2. **Chemical reaction of Cu₂O oxidation to give CuO:**
When the reaction is controlled by the surface chemical reaction, Eq. (25), the reaction rate is given by:

$$\frac{dX_{Ox}}{dt} = k_{Ox} S_{CuO} c C_{O_2}^{1/n} \left(1 - \frac{C_{O_2,eq}}{C_{O_2}}\right) f(X_{Ox})$$  \hspace{1cm} (26)$$

Similar to the reduction analysis, value of $\theta$ was calculated with Freundlich isotherm, i.e. Eq. (16). The nucleation model was also considered for the oxidation reaction. The expression for the oxidation reaction rate, including the conversion evolution function, is the following:

$$\frac{dX_{Ox}}{dt} = k_{Ox} S_{CuO} c C_{O_2}^{1/n} \left(1 - \frac{C_{O_2,eq}}{C_{O_2}}\right) \left[N^{-1}(1-X_{Ox})\left[-\ln(1-X_{Ox})\right]^{1-N}\right]$$  \hspace{1cm} (27)$$

Integrating Eq. (27) the following expression was obtained to calculate the conversion evolution with time:

$$\left[-\ln(1-X_{Ox})\right]^N = k_{Ox} S_{CuO} c C_{O_2}^{1/n} \left[1 - \frac{C_{O_2,eq}}{C_{O_2}}\right] t$$  \hspace{1cm} (28)$$

Parameters $k_{Ox}$ and $c$ could not be calculated separately for oxidation reaction. In this case, an effective kinetic constant for oxidation reaction was defined as:

$$k_{Ox}^* = k_{Ox} S_{CuO} c = k_{Ox,0} e^{-E_{Ox}/RT}$$  \hspace{1cm} (29)$$

Thus, it is necessary to determine three parameters for each temperature: $N$, $n$ and $k_{Ox}^*$. To know the best value of $N$, Fig. 8(b) shows a plot of $\left(-\ln(1-X_{Ox})\right)^N$ vs. time for different values of $N$. Linear regression of each data show the fit to a linear plot. Table 4 shows the values of the correlation coefficients for the different values of $N$. Best fitting
correspond to $N$ equal to 3/4. This procedure has been done for the conversion data obtained at each temperature analyzed in this work, obtaining the same result of $N$ for all of them.

Parameters $n$ and $k'_O$ for the oxidation reaction were obtained from a plot of $Y_{Ox}$ vs. $\ln\left(C_{Ox}\right)$ at 1173 K, as it was described by the following equation derived from Eqs. (27) and (29), for $X_{Ox} = 0.2$.

$$
Y_{Ox} = \ln\left(\frac{1}{1 - \frac{C_{Ox,eq}}{C_{Ox}} \left[N^{-1} (1 - X_{Ox}) \left(-\ln(1 - X_{Ox})\right)^{1-N}\right]^{-N}}\right) \left[-\frac{dX_{Ox}}{dt}\right]_{X_{Ox}=0.2} = \ln(k_{Ox}) + \frac{1}{n} \ln\left(C_{Ox}\right)
$$

Fig. 10(b) shows the plot and the linear regression of $Y_{Ox}$ vs. $\ln\left(C_{Ox}\right)$. A value of $n$ equal to 1.2 was obtained. Experiments at different temperatures between 1123 and 1273 K and 21 vol.% O$_2$ were considered to calculate the temperature dependence of the kinetic constant. Considering an Arrhenius dependence of $k'_O$, pre-exponential factor and activation energy can be obtained. Fig. 9 shows the Arrhenius plot for the oxidation reaction, and Table 5 shows the kinetic parameters for pre-exponential factor and activation energy obtained. An activation energy of 32 kJ mol$^{-1}$ was obtained in this work for the oxidation kinetic constant.

Finally, Fig. 5(a) shows experimental and theoretical conversion vs. time curves obtained for different O$_2$ concentrations. It can be seen that there was a good agreement between the experimental and predicted data by the kinetic model with the Freundlich isotherm. The predictions were good in all the range of O$_2$ concentrations used. This result indicates that the kinetic model with Freundlich isotherm was valid to describe the oxidation of the Cu$_2$O in a broad range of O$_2$ concentrations, even at concentrations very close to the equilibrium conditions. On the other hand, Fig. 5(b) shows
experimental and theoretical conversion vs. time curves at different temperatures. It can be seen that a very good fitting was obtained with the nucleation model.

We can conclude that with the kinetic model developed in this work, it is possible to predict the reduction and oxidation reaction rates at different oxygen concentrations and different temperatures in a broad range of operation conditions suitable for the CLOU operation process.

4. Simulation of the CLOU process with kinetic data

In order to design a CLOU system, the most important parameters are the solids inventory in the system and the oxygen carrier circulation rate. Both parameters are highly influenced by the material reactivity and its oxygen transport capacity. With the kinetic data determined in this work, the CLOU process was simulated by determining the carbon capture efficiency for different coals as a function of solids inventory and solids circulation rate.

4.1. Solids inventory and solids circulation rate to transfer oxygen from air to fuel

The solids circulation rate was calculated by an oxygen mass balance in the system. A simplified model was developed by the authors [26] and later modified for the iG-CLC process [31] for the use of solid fuels. The circulation rate of solids per MWth, \( \dot{m}_{\text{OC}} \), that depends on the composition and heat value of the solid fuel, can be calculated as:

\[
\dot{m}_{\text{OC}} = \frac{10^3 m_o}{LHV \cdot R_{\text{OC}} \cdot \Delta X_{\text{OC}}}
\]  

(31)
being the mass of oxygen required per kg of solid fuel to full combustion, as for the case of the conventional combustion with air, LHV the lower heating value of the solid fuel and $\Delta X_{OC}$ the variation of the oxygen carrier conversion in every reactor.

The circulation rate of solids between both reactors was calculated as a function of the variation of the oxygen carrier conversion and it was shown in Fig. 11 when a lignite is used, with a corresponding $m_O = 1.2$ kg oxygen per kg of coal and a LHV of 16250 kJ/mol. The circulation rate is higher at low values of $\Delta X_{OC}$, and decreases quickly when the conversion variation of the oxygen carrier at the fuel reactor increases, reaching low values when the conversion is near to 1. Abad et al. [26] estimated the maximum circulation rate feasible in a CLC plant without increased costs and with commercial experience to be 16 kg s$^{-1}$ per MW$_{th}$. This means that the minimum value of $\Delta X_{OC}$ must be 0.1 and it is necessary to operate at higher values.

The minimum mass of solids in the fuel and air reactors per MW$_{th}$ of fuel, $m_{OC}$, for the combustion of solid fuels was calculated by doing a mass balance to the fuel reactor [31]:

$$m_{OC} = \frac{10^3 m_O}{LHV \cdot R_{OC} \left( \frac{dX}{dt} \right)}$$  \hspace{1cm} (32)

The average reactivity for each reactor was obtained considering the average gas concentration in the reactor and the solids residence time distribution in the reactor as perfect mixing.

Different average oxygen concentration was assumed either in fuel or air reactor. In a CLOU process, the minimum solids inventory in the fuel reactor to transfer the required oxygen for fuel combustion corresponds to the condition where the oxygen uncoupling reaction rate is maximized. This condition is reached when the oxygen concentration in
Eq. (20) is considered to be zero, corresponding to the asymptotic limit in which all the O₂ released is consumed by the fuel and there is not an excess of O₂ in gases [25].

On the other hand, the solids inventory in the air reactor was calculated considering an air excess of 20%. The average oxygen concentration in the air reactor was those that fulfil Eq. (33), in this case 11 vol.%; see reference [26] for more information.

\[
\frac{\Delta X_g}{dt} = \int_{X_{g,in}}^{X_{g,out}} \frac{dX_g}{dt} \bigg|_{O_2} \tag{33}
\]

The residence time distribution of particles in the reactor was also considered to calculate the average reaction rate. Assuming perfect mixing of solids in the reactors, the average reaction rate was calculated as [26]:

\[
\frac{dX_i}{dt} = \int_0^t \frac{dX_i}{dt} e^{-\frac{t-t_i}{t_w}} dt \tag{34}
\]

This equation considers particles enter to the reactor partially converted. The reaction time necessary to reach complete conversion will be \(t_c\), being this value the upper limit of the integration of Eq. (34). Following the method presented in [26], \(t_c\) is defined here for the nucleation model as:

\[
t_c = \frac{1}{k} \left(-\ln \frac{X_{\text{red, in FR}}}{X_{\text{red, in FR}}} \right)^{\frac{1}{4}} \tag{35}
\]

Thus, initial reaction rate was calculated for conversion \(X_{\text{red}} = 0\), and \(t_c\) corresponded to the time reaching complete reduction, in this case for \(X_{\text{red}} = 1 - X_{\text{red, in FR}}\).

The expression that describe the reactivity using a nucleation model is the following

\[
\frac{dX_{\text{red}}}{dt} = \frac{4}{3} \frac{k^2}{kT^{1/3}} e^{-kT^{1/3}} \tag{36}
\]

Parameter \(k\) includes the kinetic constant and the function of the oxygen concentration.
\[ k = k'_{\text{red}} \left( 1 - C_{O_2}^{1/2} \right) \left( 1 - \frac{C_{O_2}}{C_{eq}} \right) \]  \hspace{1cm} (37)

\( t_m \) is the mean residence time of the oxygen carrier particles in the fuel reactor, which is dependent on the solid recirculation rate and on the reactor size.

\[ t_m = \frac{m_{\text{OC,FR}}}{\dot{m}_{\text{OC}}} = \frac{\Delta X_{\text{Red}}}{\frac{dX_{\text{Red}}}{dt}} \]  \hspace{1cm} (38)

The average reactivity has been expressed to consider that the oxygen carrier can be introduced to the fuel reactor with a mean solid conversion reduction, \( \overline{X}_{\text{Red,inFR}} \), higher than 0. Following nucleation model, it was assumed that the unconverted solid was in the surface of the particle. It is worth noting that the minimum oxygen inventory calculated in this section is a function of the oxygen carrier reactivity, and corresponds to the amount of solids to supply oxygen at the required rate determined by the coal feeding rate. Later on, the oxygen consumption by the coal will be further analysed, which will depend on the coal reactivity.

The minimum oxygen carrier inventory in the fuel or air reactor was calculated considering complete conversion in each reactor. Fig. 11 shows the minimum oxygen carrier inventories for both fuel and air reactor as a function of the variation in the oxygen carrier conversion at 1223 K. It can be seen that low values of variation of oxygen carrier conversion gives high values of oxygen carrier circulation rate and low amount of solid inventories in both reactors. If a value of \( \Delta X_{\text{OC}} = 0.1 \) was assumed, the minimum values of oxygen carrier inventories are 160 kg/MWth and 95 kg/MWth for the fuel and air reactor, respectively. A high solid inventory in the fuel reactor (235 kg/MWth) was experimentally used in combustion tests in a 1.5 MWth CLOU unit with this oxygen carrier [8]. However, there was an O₂ excess at the fuel reactor exit,
therefore lower inventories would be possible in that unit with complete combustion of the fuel.

4.2. Carbon capture efficiency for different fuels

In addition to the solids inventory needed to transfer the required oxygen to full combustion determined by the coal feeding rate, it is necessary to reach high combustion efficiency in the fuel reactor. So, the solids residence time in the fuel reactor must allow the char conversion, which is related to the CO₂ capture efficiency. It is worth noting that unconverted char in the fuel reactor reaches the air reactor, where it will be burnt to CO₂ which is not captured. Thus, the CO₂ capture efficiency would depend on the solid inventory in the fuel reactor.

The performance of the fuel reactor in a CLOU system is influenced by the pseudo-equilibrium reached between the oxygen released by the oxygen carrier and the oxygen consumed by fuel. Therefore, the oxygen balance in the fuel reactor must consider the oxygen release from the oxygen carrier and the different uses of this oxygen, for conversion of char, volatiles and O₂ concentration in gas stream:

\[
(-r_2)_{OC} = \left(r_{OC} \right)_C + \left(r_{red} \right)_{red} + \left(r_{gas} \right)_{gas}
\]  

(39)

The oxygen release rate depends on the oxygen carrier reactivity and the oxygen concentration in the reactor

\[
(-r_2)_{OC} = R_{OC} m_{OC,FR} \left[ \frac{dX_{red}}{dt} \right]
\]  

(40)

The oxygen released from the oxygen carrier is used to:
1. To burn carbon in char particles. During TGA tests of char combustion with gaseous $O_2$, constant reaction rate with time was observed [10, 32]. Thus, the char reaction rate can be calculated by

$$ (r_{\text{char}})_C = \frac{M_{O_2} m_{\text{char}}}{M_C} \left[ \frac{dX_C}{dt} \right] $$

(41)

2. To burn volatile matter. It is assumed complete combustion of volatile matter. The oxygen reacted with volatile matter is the difference between the oxygen demand of the solid fuel fed and the oxygen demand of the fixed carbon.

$$ (r_{\text{vol}})_{\text{vom}} = m_{\text{vom}} \left[ m_{O_2} - \frac{M_{O_2}}{M_C} [C_{\text{fix}}] \right] $$

(42)

3. To accumulate in the exit gas stream. Oxygen can be present in the gaseous stream from the fuel reactor, but always at concentrations below the equilibrium concentration at the reactor temperature. The rate of oxygen release in the gaseous stream depends on the gas at the fuel reactor exit, which in turn depends on the gas inlet to the fuel reactor inlet.

$$ (r_{\text{gas}})_{\text{gas}} = M_{O_2} [F_{\text{gas}} Y_{O_2}]_{\text{fuel FR}} $$

(43)

$(r_{\text{gas}})_C$ only depends on oxygen concentration and $(r_{\text{char}})_C$ also depends on char concentration in the fuel reactor. To determine the char concentration, a carbon balance was done considering the different streams where carbon is: carbon in fuel, carbon in volatiles, carbon in converted char in the fuel reactor, and carbon in the solids stream from the fuel reactor.

$$ F_{C,\text{SF}} = F_{C,\text{vol}} + X_C F_{C,\text{char}} + (1 - X_C) F_{C,\text{char}} $$

(44)

Each carbon flow is calculated as:
\[ F_{C,coal} = \frac{1}{M_C} \dot{m}_{coal} \left[ C_{coal} \right] \]  
(45)

\[ F_{C,vol} = \frac{1}{M_C} \dot{m}_{coal} \left[ C_{coal} - C_{fix} \right] \]  
(46)

\[ F_{C,char} = \frac{1}{M_C} \dot{m}_{coal} \left[ C_{fix} \right] \]  
(47)

\[ (1 - X_c) F_{C,char} = \frac{1}{M_C} \dot{m}_{OC} \frac{f_{C,FR}}{1 - f_{C,FR}} (1 - \eta_{CSS}) \]  
(48)

\[ f_c \] being the mass fraction of carbon in solids in the fuel reactor:

\[ f_c = \frac{m_{C,FR}}{m_{OC,FR} - m_{C,FR}} \]  
(49)

The char fraction \( f_c \) affects to the solids transfer to the air reactor and the oxygen consumed in the fuel reactor. The effect of a carbon stripper efficiency, \( \eta_{CSS} \), on char conversion is also considered in Eq. (48). A carbon stripper makes a selective recirculation of unconverted char particles to the fuel reactor from the solids stream exiting the fuel reactor in order to minimize the flow of unconverted carbon in the air reactor [32], thus obtaining high CO\(_2\) capture efficiencies [10, 32].

By fixing the mass of oxygen carrier in the fuel reactor, an iterative process can be done modifying the oxygen concentration and the mass fraction of carbon in the fuel reactor to obtain the oxygen generation rate and the consumption rate in Eqs. (40) and (41). The objective of the iterative process was to fulfil simultaneously the oxygen and carbon balances showed in Eqs. (39) and (44). Once each carbon flow is known, the CO\(_2\) capture efficiency, \( \eta_{CC} \), can be obtained for the assumed solids inventory.

\[ \eta_{CC} = \frac{F_{C,vol} + X_c F_{C,char}}{F_{C,coal}} \]  
(50)
It is worth noting that the CO\textsubscript{2} capture efficiency also depends on the solids circulation flow rate because: (1) the circulation of solids affects to the solids residence time, and therefore to the reactivity of oxygen carrier; and (2) affects to the carbon flow exiting the fuel reactor.

In this work, three fuels have been considered for the analysis: a high reactive bituminous coal (HRB), a low volatile bituminous coal (LVB) and a lignite. These coals were tested before at the continuous CLOU 1.5 kW\textsubscript{th} unit [8, 10], showing different behaviour during the combustion tests. The char reactivity kinetic parameters needed for this study have been taking from Hurt and Mitchell [33]. Proximate and ultimate analysis and the corresponding kinetic parameters are shown in Table 6 for each coal.

Fig. 12(a) shows the O\textsubscript{2} concentration at the fuel reactor outlet as a function of the oxygen carrier conversion using the lignite fuel and different fuel reactor solid inventories (150, 250, 500 and 1500 kg/MW\textsubscript{th}). Fuel reactor temperature was 1223 K and the use of a carbon separation system (\(\eta_{CSS} = 0\)) was not considered. The O\textsubscript{2} concentration at equilibrium conditions is also included for comparison purposes. It can be observed that the oxygen concentration decreases when the variation of the conversion increases. This is due to the fact that more coal is converted in the fuel reactor and the average oxygen carrier reactivity decreases as \(\Delta X_{OC}\) increases, see Eq. (39). It can be also seen that the oxygen concentration increases when the solids inventory in the fuel reactor increases, because there is more oxygen in solids available for oxygen uncoupling. Underline that when the CO\textsubscript{2} capture efficiency is low there are O\textsubscript{2} at the fuel reactor outlet. This means, that this oxygen carrier is highly reactive and can release O\textsubscript{2} although the residence time in the fuel reactor is not enough to convert completely the char.
Fig. 12(b) shows the CO$_2$ capture efficiency as a function of the variation of the oxygen carrier conversion for same conditions. CO$_2$ capture efficiency increases when the solid inventory and the oxygen carrier conversion increase due to the associated increase in the solids residence time. Note that all lines converge to a CO$_2$ capture value of 24% at $\Delta X_{OC} = 0$ which corresponds to the combustion of the volatile matter of this coal. At high values of the solids conversion, the increase in the CO$_2$ capture efficiency is smoother. This behaviour is due to two additive reasons: 1) the residence time in the fuel reactor is inversely proportional to the conversion variation, producing that the char conversion is not proportional to the variation of oxygen carrier conversion; 2) a less O$_2$ concentration in the fuel reactor decrease the char conversion rate in the fuel reactor. In fact, the CO$_2$ capture efficiency can decrease slightly at high values of $\Delta X_{OC}$. Therefore, a maximum in the CO$_2$ capture efficiency for each solids inventory in the fuel reactor was observed by changing the solids conversion variation. This maximum is due to the oxygen concentration decrease toward 0, and the effect of low oxygen concentration on the decrease of the char combustion rate is higher than the beneficial effect of the residence time increase.

CO$_2$ capture efficiencies higher than 90% can be only reached with oxygen carrier inventories higher than 500 kg/MW$_{th}$ and $\Delta X_{OC} > 0.5$, without the use of a carbon separation system ($\eta_{CSS} = 0$). Therefore, it is recommended to work with high values of $\Delta X_{OC}$, i.e. low solids circulation rate to obtain high CO$_2$ capture efficiencies.

Fig. 13(a) shows the O$_2$ concentration at the outlet of the fuel reactor as a function of the fuel reactor solids inventory for the three different coals (HRB, lignite and LVB). Fuel reactor temperature was 1223 K and the use of a carbon separation system ($\eta_{CSS} = 0$) was not considered. It can be observed that the O$_2$ concentration increases with the inventory in the fuel reactor due to the increase of solids generating oxygen. The O$_2$
concentration is very similar for the lignite and LVB, but it is lower for the HRB, due to the high amount of volatiles that the HRB contains, which consume more O₂. As an example, for fuel reactor solids inventories <600 kg/MWₘₜ, oxygen concentrations at fuel reactor outlet are of the order of 1 vol.% which are lower than that found in oxy-combustion process for coal.

The effect of fuel reactor solids inventory on the CO₂ capture efficiency was also evaluated for the different coals: HRB, lignite and LVB. Fig. 13(b) shows the variation of the CO₂ capture efficiency as a function of the solid inventory in the fuel reactor for these coals at the same conditions, but considering a solid conversion variation of ΔXOC = 0.7. In all cases the CO₂ capture efficiency increases with the solids inventory because of a higher solid residence time and higher oxygen availability. It can be seen that for the high reactive coals, i.e. HRB and lignite, it is possible to reach high CO₂ capture efficiencies (≥95%) with around 600 kg/MWₘₜ in the fuel reactor. However, for low reactive coals, i.e. LVB, it is necessary higher values of solids inventory to achieve high CO₂ capture efficiency, with values near 1500 kg/MWₘₜ. Moreover, Fig 13(b) shows experimental results obtained in the 1.5 kWₘₜ continuous unit for CLOU process with different coals: HVB, lignite and LVB [8,10]. It can be seen that experimental results match with data obtained from the model for each coal simulated. Fig. 13(b) also shows the CO₂ capture efficiency for a LVB when a carbon stripper with a 90% of efficiency was included in the simulation. It can be seen the important effect of this separation unit allowing high CO₂ capture efficiencies even with low values of solids inventories, 99% with 700 kg/MWₘₜ. Therefore, for low reactive coals it is necessary to use a carbon stripper to reach high CO₂ capture rates. But even for reactive coals, the use of an efficient carbon tripper reduces also the oxygen carrier inventories in the fuel reactor and the SO₂ emissions in the air reactor [11, 34].
It is worth noting that the fuel reactor solids inventory needed to supply the stoichiometric oxygen flow rate to burn a lignite (about 300 kg/MW\textsubscript{th}, with $\Delta X_{OC} = 0.7$; see Fig. 11) is lower than the solids inventory needed to reach a CO\textsubscript{2} capture higher than 95% without a carbon stripper ($\approx 600$ kg/MW\textsubscript{th}). This fact agree with previous results obtained from the analysis of the oxygen carrier reactivity [25] and results obtained in a CLOU unit [8, 10]. It can be concluded that the kinetic parameters determined together with the simulation tool developed in this work, configure a useful instrument for the design and optimization of CLOU process.

5. Conclusions

Reaction rates of reduction and oxidation of a Cu-based oxygen carrier (60 wt.% of CuO and 40 wt.% of MgAl\textsubscript{2}O\textsubscript{4}) for CLOU process has been measured by TGA to determine the redox kinetic. Relevant reactions were decomposition of CuO to Cu\textsubscript{2}O and oxidation of Cu\textsubscript{2}O to CuO. A nucleation model for the variation of the solid conversion with time and a Langmuir-Hinshelwood surface kinetic control together with Freundlich’s isotherm was valid to predict the experimental data in a broad range of O\textsubscript{2} concentration and temperatures. In fact good predictions were obtained even at O\textsubscript{2} concentrations very close to the equilibrium conditions.

The kinetic model was further used to analyze the design and operation conditions of CLOU process using this oxygen carrier. Minimum solids inventory of 160 kg/MW\textsubscript{th} in the fuel reactor and 95 kg/MW\textsubscript{th} in air reactor were determined to transfer the oxygen flow demanded for full combustion of the coal. The CO\textsubscript{2} capture efficiency as a function of the oxygen carrier circulation rate and the fuel reactor solids inventory for three different coals have been also estimated. For high reactive coals, i.e. HRB and
lignite, it would be possible to reach high CO₂ capture rates (≥95%) with 600 kg/MWₘₚ. However, for low reactive coals, i.e. LVB, 1500 kg/MWₘₚ would be needed to achieve high CO₂ capture efficiencies. These results highlight the need of using an efficient carbon stripper which allows CO₂ capture efficiencies higher than 95% with low solids inventories.

Solids flux hydrodynamic limit (····) also shown.

Fig. 12. (a) \( O_2 \) concentration at the fuel reactor outlet and (b) \( CO_2 \) capture efficiency as a function of the variation of oxygen carrier conversion in the fuel reactor using lignite as fuel and different solids inventories in the fuel reactor: 1500(-----), 500 (····), 250 (---) and 150 (···-) kg/MW\(_{th}\). \( T_{FR} = 1223 \) K, \( \eta_{CSS} = 0 \).

Fig. 13. (a) \( O_2 \) concentration at the fuel reactor outlet and (b) \( CO_2 \) capture efficiency, as a function of the fuel reactor inventory for three different coals: HRB (-----), lignite (····), LVB (-----), \( T_{FR} = 1223 \) K, \( \eta_{CSS} = 0\%\), \( \Delta \chi_{OC} = 0.7 \). LVB with a \( \eta_{CSS} = 90\% \) also shown (···-). Experimental points obtained in the 1.5 kW\(_{th}\) continuous unit for CLOU process: HRB (▼) [8], lignite (●), LVB (▲) [10].
Fig. 1. Schematic layout of the CLOU system.
Fig. 2. Equilibrium oxygen concentration over the CuO/Cu$_2$O system as a function of temperature.
Fig. 3. Effect of temperature (a) $y_{O_2} = 0$ vol. %, and (b) $y_{O_2} = 1.5$ vol. %, on the oxygen carrier reduction rate using N$_2$. Symbols, experimental data; continuous line, model predictions.
Fig. 4. Effect of oxygen concentration (vol.%) at 1273 K on the oxygen carrier reduction, using N$_2$+O$_2$ mixtures. Symbols, experimental data; continuous line, model predictions.
Fig. 5. Effect of (a) $O_2$ concentration (vol.%) at 1173 K and (b) temperature with a $y_{O_2} = 21$ vol.%, on the oxygen carrier oxidation. Symbols, experimental data; continuous line, model predictions.
Fig 6. Arrhenius plots to calculate global activation energy in Eq. (6): ●, reduction; ▲, oxidation; for the Cu60MgAl.
Fig. 7. Effect of the oxygen concentration in the reaction order of Eq. (7) for: (a) reduction; (b) oxidation.
Fig. 8. Determination of $N$ parameter using conversion data to calculate $(-\ln(1-X))^N$ vs time (Eq. (21)) at (a) $1273$ K, 4 vol.% O$_2$ for reduction; and (b) $1173$ K, 6 vol.% O$_2$ for oxidation.
Fig. 9. Temperature dependence of kinetic parameters for Cu60MgAl: kinetic constant for oxygen uncoupling (●); kinetic constant for oxidation (▲); and adsorption parameter c for reduction (■).
Fig. 10. Determination of (a) \( n \) and \( c \) parameters using Eq. (23) for reduction; and (b) \( n \) parameter using Eq. (30) for oxidation reactions.
Fig. 11. Minimum solids inventories per MWth: fuel reactor (- - -), air reactor (- - - -); and specific circulation rate of solids (——) using a lignite as a function of the variation of the oxygen carrier conversion between the fuel and air reactors. $T = 1223$ K. Solids flux hydrodynamic limit (· · · ·) also shown.
Fig. 12. (a) O₂ concentration at the fuel reactor outlet and (b) CO₂ capture efficiency as a function of the variation of oxygen carrier conversion in the fuel reactor using lignite as fuel and different solids inventories in the fuel reactor: 1500(——), 500 (⋯⋯), 250 (---) and 150 (⋯⋯) kg/MWth. $T_{FR} = 1223$ K, $\eta_{CSS} = 0$. 
Fig. 13. (a) O$_2$ concentration at the fuel reactor outlet and (b) CO$_2$ capture efficiency, as a function of the fuel reactor inventory for three different coals: HRB (——), lignite (···), LVB (-----), $T_{FR} = 1223$ K, $\eta_{CCS} = 0\%$, $\Delta X_{OC} = 0.7$. LVB with a $\eta_{CSS} = 90\%$ also shown (--) . Experimental points obtained in the 1.5 kW$_{th}$ continuous unit for CLOU process: HRB (▼) [8], lignite (●), LVB (▲) [10].
