Search for production of an $\Upsilon(1S)$ meson in association with a $W$ or $Z$ boson using the full 1.96 TeV $p\bar{p}$ collision data set at CDF
Production of the $\Upsilon(1S)$ meson in association with a vector boson is a rare process in the standard model with a cross section predicted to be below the sensitivity of the Tevatron. Observation of this process could signify contributions not described by the standard model or reveal limitations with the current nonrelativistic quantum-chromodynamic models used to calculate the cross section. We perform a search for this process using the full Run II data set collected by the CDF II detector corresponding to an integrated luminosity of $9.4 \text{ fb}^{-1}$. The search considers the $\Upsilon \rightarrow \mu\mu$ decay and the decay of the $W$ and $Z$ bosons into muons and electrons. In these purely leptonic decay channels, we observe one $\Upsilon W$ candidate with an expected background of $1.2/\sqrt{5}$ events, and one $\Upsilon Z$ candidate with an expected background of $0.1/\sqrt{5}$ events. Both observations are consistent with the predicted background.
contributions. The resulting upper limits on the cross section for $Y + W/Z$ production are the most sensitive reported from a single experiment and place restrictions on potential contributions from non-standard-model physics.

I. INTRODUCTION

The standard model production of an upsilon ($Y$) meson in association with a $W$ boson or a $Z$ boson is a rare process whose rate was first calculated in Ref. [1], where $YW$ and $YZ$ production occur through the parton-level processes producing $W + b\bar{b}$ and $Z + b\bar{b}$ final states, in which the $b\bar{b}$ pair may form a bound state (either an $Y$ or an excited bottomonium state that decays to an $Y$). More recently, rates for these processes have been calculated at next-to-leading order in the strong-interaction coupling for proton-antiproton ($p\bar{p}$) collisions at 1.96 TeV center-of-mass energy and proton-proton collisions at 8 and 14 TeV [2].

The cross sections calculated for $YW$ and $YZ$ production in $p\bar{p}$ collisions at 1.96 TeV are 43 fb and 34 fb, respectively. These values were calculated at leading order using the MADONIA quarkonium generator [3] as detailed below and are roughly a factor of 10 smaller than the earlier calculations from Ref. [1]. The calculations of these processes are very sensitive to nonrelativistic quantum-chromodynamic (NRQCD) models, especially the numerical values of the long-distance matrix elements (LDME), which determine the probability that a $b\bar{b}$ will form a bottomonium state. Measurements of $Y + W/Z$ cross sections are important for validating these NRQCD models.

Supersymmetry (SUSY) is an extension of the standard model (SM) which has not been observed. Reference [1] describes some SUSY models in which charged Higgs bosons can decay into $YW$ final states with a large branching fraction ($B$). Similarly, in addition to the expected decays of a SM Higgs to an $YZ$ pair, forward light neutral scalars may decay into $YZ$. Therefore, if the observed rate of $YW$ and/or $YZ$ production is significantly larger than the predicted SM rate, it may be an indication of physics not described by the SM.

In 2003, the CDF collaboration reported [4] a search for the associated production of an $Y$ meson and a $W$ or $Z$ boson. In that analysis, a sample corresponding to 83 pb$^{-1}$ of 1.8 TeV $p\bar{p}$ collision data collected with the Run I CDF detector was used to set upper limits on the production cross sections ($\sigma$) at the 95% confidence level (C.L.) of $\sigma(p\bar{p} \rightarrow YW) \times B(Y \rightarrow \mu^+\mu^-) < 2.3$ pb and $\sigma(p\bar{p} \rightarrow YZ) \times B(Y \rightarrow \mu^+\mu^-) < 2.5$ pb. The ATLAS collaboration has also reported on the related channels of $J/\psi + W/Z$ production [5,6].

Here we present a search for $Y + W/Z$ production, using a sample corresponding to 9.4 fb$^{-1}$ of 1.96 TeV $p\bar{p}$ collision data collected with the CDF II detector. We use the dimuon decay channel to identify the $Y$ meson. We use only the electron and muon decay channels of the $W$ and $Z$ bosons, which give the best sensitivities for this search.

II. THE CDF DETECTOR

The CDF II detector is a nearly azimuthally and forward-backward symmetric detector designed to study $p\bar{p}$ collisions at the Tevatron. It is described in detail in Ref. [7]. It consists of a magnetic spectrometer surrounded by calorimeters and a muon-detection system. Particle trajectories are expressed in a cylindrical coordinate system, with the $z$ axis along the proton beam and the $x$ axis pointing outward from the center of the Tevatron. The azimuthal angle ($\phi$) is defined with respect to the $x$ direction. The polar angle ($\theta$) is measured with respect to the $z$ direction, and the pseudorapidity ($\eta$) is defined as $\eta = -\ln(\tan(\frac{\theta}{2}))$. The momentum of charged particles is measured by the tracking system, consisting of silicon strip detectors surrounded by an open-cell drift chamber, all immersed in a 1.4 T solenoidal magnetic field. The tracking system provides charged-particle trajectory (track) information with good efficiency in the range $|\eta| \lesssim 1.0$. The tracking system is surrounded by pointing-geometry tower calorimeters, that measure the energies of electrons, photons, and jets of hadronic particles. The electromagnetic calorimeters consist of scintillating tile and lead absorber, while the hadronic calorimeters are composed of scintillating tiles with steel absorber. The calorimeter system includes central and plug subdetectors, with the central region covering $|\eta| < 1.1$ and the plug region covering the range $1.1 < |\eta| < 3.6$. The muon system is composed of planar multiwire drift chambers. In the central region, four layers of chambers located just outside the calorimeter cover the region $|\eta| < 0.6$. An additional 60 cm of iron shielding surrounds this system, and behind that is a second subdetector composed of another four layers of chambers. A third muon subdetector covers the region 0.6 $< |\eta| < 1.0$, and a fourth subdetector extends coverage to $|\eta| < 1.5$. Cherenkov luminosity counters measure the rate of inelastic collisions, that is converted into the instantaneous luminosity. A three-level online event-selection system (trigger) is used to reduce the event rate from 2.5 MHz to approximately 100 Hz. The first level consists of specialized hardware, while the second is a mixture of hardware and fast software algorithms. The software-based third-level trigger has access to a similar set of information to that available in the off-line reconstruction.
III. MONTE CARLO AND DATA SAMPLES

We use a number of quantities based on track and calorimeter information in the event selection. The transverse momentum of a charged particle is $p_T = p \sin \theta$, where $p$ is the particle’s momentum. The analogous quantity measured with the calorimeter is transverse energy, $E_T = E \sin \theta$. The missing transverse energy, $E_T$ is defined as $\vec{E}_T = -\sum_i E_i \hat{n}_i$, where $\hat{n}_i$ is a unit vector perpendicular to the beam axis and pointing to the center of the $i$th calorimeter tower. The $\vec{E}_T$ is adjusted for high-energy muons, which deposit only a small fraction of their energies in the calorimeter, and off-line corrections applied to the measured energies of reconstructed jets [8] which result from the hadronization of quarks and gluons. We define $E_T = |\vec{E}_T|$. The invariant mass of two leptons is $M_{\ell\ell} = (E_1 + E_2)^2/c^4 - (p_{T1} + p_{T2})^2/c^2$, and the transverse mass of a lepton and neutrino (estimated with $E_T$) is $M_T = \sqrt{2E_T p_T (1 - \cos \xi)/c^2}$, where $\xi$ is the angle between the lepton track and $E_T$ vector in the transverse plane. For muons, $p_T$ and $p_T$ are used rather than their measured energies $E_\ell$ and $E_\ell$ in the definitions of $M_{\ell\ell}$ and $M_T$.

The analysis uses events selected with triggers requiring a high-$E_T$ central electron candidate ($E_T > 18$ GeV, $|\eta| < 1.0$) or a high-$p_T$ central muon candidate ($p_T > 18$ GeV/c, $|\eta| < 1.0$). The integrated luminosity of these samples is 9.4 fb$^{-1}$. All the search channels include the $Y \rightarrow \mu\mu$ signal, so we only use data acquired when the muon detectors were operational, resulting in the same integrated luminosity for the electron and muon samples.

We also use a low-$p_T$ dimuon-triggered $Y$ sample to estimate one of the backgrounds as detailed in Sec. V. The dimuon invariant-mass distribution from this low-$p_T$ sample, whose integrated luminosity is 7.3 fb$^{-1}$, is shown in Fig. 1 for the mass range in the region of the $Y$ resonances.

We produce simulated event samples of the signal processes, $YW$ and $YZ$, by first generating events with MADGRAPH [9] and its quarkonium extension MADONIA [3]. We include all $YW$ and $YZ$ processes from Ref. [1] and the LDME values relevant for the Tevatron from Ref. [10]. An explanation of how LDME values are determined from fits to quarkonia data is given in Ref. [11], although the values obtained in this reference are specific for the LHC. PYTHIA [12] is used to simulate the $Y$, $W$, and $Z$ decays and parton showering. Generated $Y$ mesons are forced to decay to two muons. We use a GEANT3-based [13] detector simulation to model the response of the CDF II detector [14].

IV. EVENT SELECTION

Events are selected with $Y$ mesons decaying to muon pairs and decays of vector bosons resulting in at least one electron or muon. In this analysis we have two categories of lepton candidates: low-$p_T$ muon candidates with $1.5 < p_T < 15$ GeV/c from the $Y$ decay and high-$E_T$ (or $p_T$) electron (or muon) candidates from the $W$ or $Z$ decay.

High-$E_T$ electron candidates are identified by matching a track to energy deposited within the calorimeter. Muon candidates are formed from charged particle tracks matched to minimum ionizing energy deposition in the calorimeter, which may or may not be matched to track segments in the muon chambers situated behind the calorimeters. Lepton reconstruction algorithms are described in detail elsewhere [15].

Electron candidates are distinguished by whether they are found in the central or forward calorimeters ($|\eta| > 1.1$) where only silicon tracking information is available. The electron selection relies on track quality, track-calorimeter matching, calorimeter energy, calorimeter profile shape, and isolation information. Most muon candidates rely on direct detection in the muon chambers, which are distinguished by their acceptance in pseudorapidity: central muon detectors ($|\eta| < 0.6$), central muon extension detectors ($0.6 < |\eta| < 1.0$), and the intermediate muon detector ($1.0 < |\eta| < 1.5$). Remaining muon candidates rely on track matches to energy deposits consistent with a minimum ionizing charged particle in the central and forward electromagnetic calorimeters respectively, and which fail to have an associated track segment in the muon subdetectors. All high-$E_T$ (or $p_T$) leptons are required to be isolated by imposing the condition that the sum of the transverse energy of the calorimeter towers in a cone of $\Delta R \equiv \sqrt{(\Delta \phi)^2 + (\Delta \eta)^2} = 0.4$ around the lepton is less than 10% of the electron $E_T$ (muon $p_T$).

The analysis uses the high-$E_T$ electron triggered, and high-$p_T$ muon triggered, data sets where events are additionally required to contain $Y(1S)$ candidates using the $Y$ decay to two low-$p_T$ muons ($1.5 < p_T < 15$ GeV/c). We define the $Y(1S)$ region as the invariant-mass range $9.25 < M_{\mu\mu} < 9.65$ GeV/c$^2$. We do not use $Y(2S)$ or

![FIG 1](color online). Dimuon invariant-mass spectrum in CDF II data from events contained within the low-$p_T$ dimuon-triggered sample. Shown are the defined $Y$ signal region and the sideband regions used for background determination.
Y(3S) decays. We define two sideband regions, $8.00 < M_{\mu\mu} < 9.00 \text{ GeV}/c^2$ and $10.75 < M_{\mu\mu} < 11.75 \text{ GeV}/c^2$, for obtaining background estimates. Events are required to have at least two low-$p_T$ muon candidates whose invariant mass lies within the Y(1S) region. To increase the efficiency for reconstructing Y candidates, we use looser quality requirements on these low-$p_T$ muon candidates than for the high-$p_T$ muon candidates used in the vector-boson reconstruction. In particular, there are no isolation requirements on the Y muon candidates, and geometrical matching requirements between charged particles in the tracker and track segments in the muon detectors are less stringent. Most low-$p_T$ muon candidates surviving event selection are found to be within acceptance of the muon chambers ($|\eta| < 1.5$). In the small fraction of events (less than 2%) that have more than two low-$p_T$ muons identified, we randomly choose one pair of those muons.

We then look for additional high-energy electron (or muon) candidates consistent with the decay of a vector boson. Events with exactly one high-energy lepton candidate, $\ell'$, which will henceforth refer to an electron or muon, with $E_T(p_T)$ greater than 20 GeV (GeV/c), in addition to the $Y \rightarrow \mu^+\mu^-$ candidate, and significant missing transverse energy ($E_T > 20$ GeV) are selected as $Y + (W \rightarrow \ell\nu)$ candidates. Such candidates are further required to have a transverse mass in the range $50 < M_T < 90 \text{ GeV}/c^2$, as expected from a $W$ boson decay. Figures 2 and 3 show the distributions of these quantities as predicted from the simulated $Y + W$ event samples.

Events with two oppositely charged high-energy lepton candidates of same flavor are selected as $Y + (Z \rightarrow \ell'^+\ell'^-)$. The $Y + (Z \rightarrow \ell\ell')$ candidates are selected by requiring one additional high-$E_T(p_T)$ electron (muon) candidate with $E_T(p_T) > 20$ GeV (GeV/c) and a second candidate with the same flavor but opposite charge and $E_T(p_T) > 15$ GeV (GeV/c). Both additional lepton candidates are required to be isolated and have an invariant mass in the range $76 < M_{\ell\ell} < 106 \text{ GeV}/c^2$. The invariant-mass distribution predicted from the simulated $Y + (Z \rightarrow \ell\ell')$ event samples is shown in Fig. 4.

The total signal efficiencies, after all selection criteria are applied, are determined from simulated event samples to be 1.8% for $Y + (W \rightarrow e\nu)$, 1.3% for $Y + (W \rightarrow \mu\nu)$, 1.8% for $Y + (Z \rightarrow e\nu)$, and 1.4% for $Y + (Z \rightarrow \mu\nu)$ events. These efficiencies do not include the branching fractions for $Y \rightarrow \mu\mu$ and the electronic and muonic decays of the vector bosons. The low acceptances are primarily driven by the geometric acceptance of the drift chamber for the two low-$p_T$ muons from the $Y$ decay. We expect a small contribution to the $W \rightarrow \ell\nu$ acceptance from $W \rightarrow \tau\nu$ events where the tau lepton decays to an electron or muon. The contribution is determined to be less than 2% of the acceptance, and is therefore neglected. The contribution
from $Z \rightarrow \tau\tau$ events to the $Z \rightarrow \ell\ell$ channels is found to be negligible.

Summaries of the selection criteria and their associated efficiencies are given in Tables I and II.

### V. BACKGROUNDS

There are two main background contributions to the samples of $YW$ and $YZ$ signal candidates after the final selection: events containing a correctly identified $W/Z$ candidate and a misidentified $Y$ candidate (real $W/Z+$ fake $Y$) and those with a correctly identified $Y$ candidate and a misidentified $W/Z$ candidate (real $Y+$ fake $W/Z$). Generic dimuon backgrounds, originating predominantly from $bb$ production, contribute events in the $Y(1S)$ mass range and are the primary source of fake $Y$ candidates. Misidentification of jets as leptons can mimic the decay signatures of $W$ and $Z$ bosons. In the case of $Z$ candidates, where two leptons are required, this background is negligible.

The real $W/Z+$ fake $Y$ background contributions are estimated by counting the number of $W$ or $Z$ candidate events in the high-$p_T$ lepton data samples that additionally contain a dimuon candidate in the sideband region of the dimuon spectrum (defined in Fig. 1). An exponential fit to these sideband regions is used to determine a ratio of the areas of the signal to sideband regions, which is then applied to these numbers for an estimate of this background contribution.

The probabilities for reconstructed jets to be misidentified as leptons are measured in jet-enriched data samples as functions of the jet $E_T$ and lepton type, and are corrected for the contributions of leptons from $W$ and $Z$ boson decays, as more fully described in Ref. [16]. To estimate real $Y+$ fake $W/Z$ background contributions, we select from the low-$p_T$ dimuon data sample events containing a high-$E_T$ jet instead of a high-$E_T (p_T)$ isolated lepton candidate that otherwise satisfy the full selection criteria. Background estimates are obtained using the measured probabilities associated with each of the jets within these events as weighting factors on the potential contribution of each. The low-$p_T$ dimuon sample is relied upon to extract these background estimates because a strong correlation between high-$p_T$ lepton trigger selection requirements and jet-to-lepton misidentification rates renders the high-$p_T$ lepton data set unsuitable for the chosen methodology. To interpolate between the two samples, additional small corrections are applied to account for differences in the integrated luminosities of the two samples and $Y$ selection inefficiencies in the low-$p_T$ dimuon sample originating from trigger requirements.

In evaluating the real $Z+$ fake $Y$ background contribution, no events containing $Y$ candidates in the sideband mass regions are observed. Background contributions to the corresponding signal samples are therefore estimated by extrapolating from the estimated real $W+$ fake $Y$ background contributions, using the ratio of $Z$ to $W$ cross sections. This makes the assumption that the probability for misidentifying a $Y(1S)$ is independent of the type of vector boson. In calculating cross-section limits, we also account for small background contributions from $YZ$
production to the $\Upsilon W$ samples, originating from events in which one of the two leptons produced in the $Z$ boson decay is not reconstructed.

VI. SYSTEMATIC UNCERTAINTIES

For determining cross-section limits we incorporate systematic uncertainties on the signal expectation and the background predictions. Systematic uncertainties on the signal expectation include those associated with the integrated luminosity measurement, low-$p_T$ muon identification, high-$E_T(p_T)$ lepton identification, high-$E_T(p_T)$ lepton trigger efficiency, theoretical modeling of the signal, and efficiencies of the event selection criteria. The upsilon-muon identification uncertainty is derived from studies that use data and simulated samples of $J/\psi \rightarrow \mu\mu$ as described in Ref. [17]. Lepton identification and trigger efficiencies are measured using samples of leptonic $Z$ decays [16]. Requirements of $E_T > 20$ GeV ($p_T > 20$ GeV/$c$) for electrons (muons) matched to lepton trigger objects ensure a uniform trigger efficiency over the lepton momentum spectra.

We use the CTEQ6L parton distribution functions (PDFs) [18] for generating the MADGRAPH samples. To estimate the acceptance uncertainty associated with the choice of PDFs, we generate additional samples using MSTW PDFs [19] and take the difference in the estimated signal acceptance as the uncertainty.

We vary the bottomonium LDMEs from Ref. [10] by one standard deviation to estimate their effect on the signal acceptance. This procedure results in an additional 6% systematic uncertainty on the signal expectation. These uncertainties correspond only to those associated with the procedure for computing LDMEs described within the cited reference. Allowing for a wider range of assumptions within the LDME calculations gives rise to additional uncertainties, which are not accounted for in this analysis. However, if an uncertainty of 20% were to be placed on the LDMEs, the cross-section limits we obtain would only increase by about 10%.

With respect to uncertainties associated with event selection criteria, we vary the $E_T$ by $\pm 10\%$ (an estimate of the $E_T$ resolution) in the simulated signal samples to quantify the effect of $E_T$ resolution.

It is possible for the $\Upsilon$ meson and the $W$ or $Z$ boson to originate from different parton-parton interactions in the same $p\bar{p}$ collision. This double-parton-scattering process is difficult to identify, but estimates have been made for several related final states using LHC and Tevatron data (see for example Ref. [5] where $J/\psi$ production in association with a $W$ boson was studied by the ATLAS collaboration). These estimates, together with a calculation using the $\Upsilon$ and vector boson cross sections at the Tevatron collision energy lead to an estimated effect of approximately $15\%$. Based on lack of knowledge on double-parton scattering, we assign this effect as a systematic uncertainty on the signal acceptance. In Table III we summarize all investigated systematic uncertainties associated with the signal expectation.

Uncertainties on predicted background contributions are also incorporated into the cross-section limits. For the real $W/Z+\tau$ fake $\Upsilon$ background, we use the statistical uncertainty originating from the small sample size in the sideband regions used for making this estimate. We assign a $50\%$ uncertainty to the real $\Upsilon+\tau$ fake $W/Z$ background based on the application of uncertainties associated with the measured jet-to-lepton misidentification rates.

VII. RESULTS

Table IV summarizes the predicted signal and background contributions, and number of observed events for each of the search samples using data from 9.4 fb$^{-1}$ of integrated luminosity at CDF. We observe one $\Upsilon + (W \rightarrow \ell\ell)$ candidate with a total expected background of $1.2 \pm 0.5$ events. In the observed $\Upsilon + (W \rightarrow \ell\ell)$ candidate the electron has $p_T = 27$ GeV, and the two muons with an invariant mass in the $\Upsilon(1S)$ region have $p_T$s of 3.8 GeV/$c$.

VIII. CONCLUSIONS

We search for \( Y + W/Z \) production using the leptonic
decay channels of the vector bosons and dimuon decay
channel of the \( Y \). The search utilizes the full CDF Run II data set.
Having observed no significant excess of events with respect to standard model predictions, we set
95% C.L. upper limits on the \( Y + W/Z \) cross sections.
The limits are \( \sigma(p \bar{p} \rightarrow YW) < 5.6 \text{ pb} \) and \( \sigma(p \bar{p} \rightarrow YZ) < 21 \text{ pb} \) which are the most stringent bounds on these
processes to date. Under the assumption that potential
non-SM physics contributions to the \( Y + W/Z \) final state
do not significantly impact the kinematic properties of
events, these limits can be interpreted as cross section
(times branching ratio to \( Y + W/Z \)) limits on non-SM
physics processes contributing to this final state. Potential
non-standard-model heavy particles decaying to \( Y + W/Z \)
final states are likely to result in leptons that are more
central than those from standard-model \( Y + W/Z \) produc-
tion and therefore provide higher signal acceptance. Hence,
the limits presented here can be considered as conservative
limits on such processes.

ACKNOWLEDGMENTS

We would like to acknowledge K. W. Lai for suggesting
the search for these processes, and thank P. Artoisenet and
