\textbf{Abstract.} We analyze the quantum fluctuations of the degenerate optical parametric oscillator close to an instability for the formation of a square pattern. While strong correlations between the fluctuations of the signal modes emitted at the critical wave number and with opposite wave vector are present both below and above threshold, no features signalling the square character of the pattern forming above threshold have been identified below threshold in the spatio-temporal second-order coherence.

\section{Introduction}

Patterns in extended nonlinear optical systems have the interesting feature of displaying noteworthy quantum aspects at room temperature, which is often not the case with more traditional fields associated with spontaneous spatial structures such as hydrodynamics, chemical reactions or biology. These quantum aspects, which arise from the quantum correlation of the spatial modes that form the pattern, have attracted the interest of researchers during the last years (see for example \cite{1-14} and Ref. \cite{15} for a review on optical pattern formation and its quantum fluctuations). For example, quantum features are found both below and above the instability threshold for pattern formation in optical parametric oscillators (OPO). In particular it has been shown that below, but close to, threshold, the quantum noise can excite the weakly damped spatial modes that will become unstable at threshold \cite{1-3}. In an isotropic system with two spatial dimensions, the spectrum of fluctuations below threshold has a radially symmetric distribution with maxima on a ring of radius equal to the wave-number of the pattern formed just above threshold. Therefore, the spectrum of fluctuations below the instability threshold is considered to be a noisy precursor \cite{16} that anticipates the above-threshold pattern wave-number. Furthermore, in optical systems where a stripe pattern is formed, strong correlations exist, even at quantum level, between the fluctuations in the number of photons emitted at the critical wave-number (|k| = k\textsubscript{c}) and opposite wave-vectors. This is an effect of the parametric coupling associated with transverse momentum conservation. It has been interpreted as a below-threshold signal of the form of the pattern that will arise above threshold, namely a stripe pattern. The fact that the correlations are associated with quantum entanglement among spatial modes has originated the term “quantum image” \cite{1}.

The most common pattern to appear above threshold in a degenerate OPO (DOPO) is a stripe pattern \cite{17} with a far field formed by two off axis beams. These beams correspond to the simultaneous emission of twin photons with a high degree of quantum correlation of their fluctuations. High above threshold a spatially disordered structure emerges in which \k\textsubscript{c} plays no particular role. Still, strong quantum correlations between pairs of opposite wavevectors persist in a one dimensional geometry \cite{18}. In the non-degenerate OPO quantum correlations are also found between the off axis emissions of the signal and idler field modes \cite{9}.

A semi-classical analysis of pattern formation in the DOPO \cite{19,20} shows that for specific values of the cavity detuning parameters, a square pattern, instead of a roll pattern, emerges. In this paper we study the quantum fluctuations and correlations at the onset of the instability that leads to the formation of a square pattern in a degenerate OPO. In particular we investigate whether below threshold there is any correlation in the fluctuations of the
far field modes with different transverse wave vectors that
can be interpreted as an anticipation of the square pattern
that appears above threshold. Since we are interested in
calculating field intensity correlation between two differ-
et space-time points, the appropriate quantity to be used
is the second order quantum correlation function g2 (see,
for example, Ref. [22]).

We show that, below threshold, the g2 function indi-
cates strong correlations between the fluctuations of the
signal critical modes with opposite wave vectors, as in
the case of stripe pattern formation. However in a continuous
model and within our rather high numerical accuracy, no
correlation is found below threshold between the fluctua-
tions of signal critical modes with wave vectors forming
an angle of $\pi/2$. These $\pi/2$-angle correlations are present
above threshold, as a consequence of the square form of
the pattern. Its presence below threshold could have been
interpreted as a quantum image of the square pattern to
emerge after the onset of the instability. Therefore below
threshold the spectrum of fluctuations provides information
about the pattern wave number (noisy precursor in the
classical sense) but does not seem to reveal or anticipa-
tate the square shape which will be formed above thresh-
hold. Furthermore, particular caution has to be taken when
interpreting g2 measurements in a truncated model ob-
tained by projecting the stochastic dynamics on just 4
modes corresponding to the square components. We show
that very close but still below threshold $\pi/2$-angle anti-
correlations in the g2 exist for this projected model. This
apparently spurious result is due to the mode-truncation and
disappears moving further below threshold and in the
continuous limit.

The article is organized as follows. In Sect. 2 we in-
troduce the continuous model used for the description of
the quantum DOPO dynamics. In Sect. 3 we define the
correlation function g2 in a way appropriate for the num-
berical calculations. In Sect. 4 we show the results of the
numerical integration of the continuous model. In Sect. 5
we introduce a truncated model with the minimal num-
ber of modes to describe the square pattern. Sect. 6 is
devoted to concluding remarks. Finally, in the Appendix
we explain the procedure we use to calculate numerically
the output field.

2 The model

We use the space dependent quantum Langevin equations
for the DOPO obtained in Ref. [3]. The system consists
in a $\chi^{(2)}$ medium enclosed in a single port cavity with
plane mirrors pumped by a coherent, monochromatic field
of frequency $2\omega$. The pump power is partially con-
vected from the pump frequency ($2\omega$) to the signal frequency $\omega$.
The intracavity pump and signal fields are described by
the space-time dependent quantum operators $A_{0}(x, t)$ and
$A_{1}(x, t)$ respectively, where $x$ represents a point in the
plane perpendicular to the direction of light propagation.

The Hamiltonian in the interaction picture is,

$$H = H_I + H_{int} + H_{ext}$$

(1)

where the free propagation of the fields, including diffraction
effects, is represented by,

$$H_I = \hbar \gamma_0 \int dx \, A_0^\dagger \left( \Delta_0 - a_0 \nabla^2 \right) A_0$$

$$+ \hbar \gamma_1 \int dx \, A_1^\dagger \left( \Delta_1 - a_1 \nabla^2 \right) A_1.$$  (2)

The constants $\gamma_0$ and $\gamma_1$ are the cavity damping rates for
the two fields; $\Delta_0 = (\omega - 2\omega)/\gamma_0$ and $\Delta_1 = (\omega_1 - \omega)/\gamma_1$
are the cavity detuning parameters ($\omega_0$ and $\omega_1$ are the
frequencies of the two longitudinal cavity modes close to
$2\omega$ and $\omega$). Parameters $a_0$ and $a_1$ are characteristic areas
that represent the strength of diffraction; and $\nabla^2$ is the two dimensional transverse Laplacian which models
the effect of diffraction in the paraxial approximation.

The term $H_{int}$ in Eq. (1) represents the nonlinear in-
teraction Hamiltonian,

$$H_{int} = \frac{i\hbar g}{2} \int dx \left( A_0 A_1^\dagger A_0^\dagger - A_0^\dagger A_1 A_0 + A_1^\dagger A_0 A_1 - A_0 A_1 A_1^\dagger \right),$$  (3)

where $g$ is the coupling parameter related to the nonlin-
erarity of the medium. The third term in Eq. (1) represents the coherent and monochromatic external driving,

$$H_{ext} = i\hbar \int dx \left( E_{in} A_0^\dagger A_0 - E_{in}^* A_0 \right),$$  (4)

where $E_{in}$ is the (scaled) plane wave pump field amplitude.

The reversible part of the dynamics is represented by
the Hamiltonian. The irreversible part is introduced in the
Liouvillean terms of the master equation for the density
matrix. The master equation can be turned into a set of
stochastic differential equations for c-number fields $\alpha_0(x, t)$ and $\alpha_1(x, t)$ corresponding to the operators $A_0(x, t)$ and $A_1(x, t)$, in the Wigner representation [3,4,15,21].

The nonlinear Langevin equations are,

$$\frac{\partial \alpha_0}{\partial t} = -\gamma_0 (1 + i \Delta_0 - ia_0 \nabla^2) \alpha_0 + E_{in} - g\alpha_1^2/2 + \sqrt{2\gamma_0} \xi_0$$

$$\frac{\partial \alpha_1}{\partial t} = -\gamma_1 (1 + i \Delta_1 - ia_1 \nabla^2) \alpha_1 + g\alpha_0 \alpha_1^* + \sqrt{2\gamma_1} \xi_1(t)$$  (5)

Variables $\xi_0$ and $\xi_1$ are white noise stochastic Gaussian
processes with zero average, and correlation,

$$\langle \xi_i(x, t) \xi_i^*(x', t') \rangle = \frac{1}{2} \delta(x - x') \delta(t - t')$$

for $i = 0, 1$. The noise terms are interpreted as vacuum
quantum noise entering through the partially transmitting
mirror.

Equations (5)-(6) can be numerically integrated to cal-
culate symmetrically ordered correlations as,

$$\langle A_0^\dagger(x, t) A_1(x', t') \rangle_{sym} =$$

$$\left\langle \frac{1}{2} \left( A_0^\dagger(x, t) A_1(x', t') + A_1^\dagger(x, t) A_0(x', t') \right) \right\rangle$$

$$= \langle \alpha_0^\dagger(x, t) \alpha_1(x', t') \rangle.$$  (6)

References:
The c-number fields outside the cavity, $\alpha_{i}^{\text{out}}(x,t)$ and $\alpha_{i}^{\text{out} \dagger}(x,t)$, corresponding to the operators $A_{i}^{\text{out}}(x,t)$ and $A_{i}^{\text{out} \dagger}(x,t)$, can be numerically calculated following the method introduced in [10]. The input-output relations,

$$\alpha_{i}^{\text{out}} = \sqrt{2}\gamma\alpha_{i} - \alpha_{i}^{\text{in}}$$

have to be discretized in order to include noise in the numerical scheme. The input fields are

$$\alpha_{i}^{\text{in}} = E_{in}/\sqrt{2\gamma} + \delta_{i} ; \quad \alpha_{i}^{\text{in}} = \xi_{i}.$$  \hspace{1cm} (9)

Appendix A contains more details on the numerical implementation of the evaluation of the output fields.

Neglecting fluctuations, eqs. (3)-(6) have a homogeneous steady state solution given by

$$\alpha_{1,s} = 0, \quad \alpha_{0,s} = \frac{E_{in}}{\gamma_{0}(1+i\Delta_{0})},$$ \hspace{1cm} (10)

This steady state homogeneous solution (10) becomes unstable as the input field is increased, and a square pattern with a critical wave number $|k_{c}| = \sqrt{-\Delta_{1}/\gamma_{1}}$ appears if $\Delta_{0} < -2\sqrt{3}$ [20]. The threshold value of the dimensionless field for the instability is,

$$\tilde{E}_{thr} = \frac{E_{thr}}{\gamma_{0}} = \sqrt{1 + \Delta_{0}^{2}}$$

where $n_{ph} = \frac{\gamma_{1}}{\gamma_{0}}$ represents the number of pump photons per unit area that are needed to reach the threshold for signal generation [15].

An analysis of the energy flux in the system can be useful, as we will see in Sect. 5, to analyze fluctuation correlations. The input and output intensities are,

$$I_{in} = h\omega|\alpha_{0}^{\text{in}}|^{2} + h\omega|\alpha_{1}^{\text{in}}|^{2}$$

$$I_{out} = h\omega|\alpha_{0}^{\text{out}}|^{2} + h\omega|\alpha_{1}^{\text{out}}|^{2}$$ \hspace{1cm} (11)

Using the input-output relations (8), the net power inside the cavity is,

$$P = \int dx(I_{in} - I_{out})$$

$$= 2h\omega \int dx \left[ 2R(E_{in}\alpha_{0}^{*}) - 2\gamma|\alpha_{0}|^{2} - \gamma|\alpha_{1}|^{2} \right]$$ \hspace{1cm} (12)

where the terms with fluctuations $\xi_{i}$ average to zero in the transverse plane. This same quantity has been used in [23] to characterise cavity soliton features in DPO. Since $P$ represents an average over the transverse plane of the net energy gain, its time average should be zero in any steady state. In Sect. 5 we use a simplified model with 4 modes to evaluate the consequences of Eq. (12).

## 3 The second order coherence function $g_{2}$

The far field of the signal outside the cavity is represented by the space Fourier transform, $A_{i}^{\text{out}}(k,t)$. The annihilation operator of the signal field defined in a small interval of wave-vectors and time, around $(k_{i}, t_{i})$, is,

$$\tilde{a}_{i} = \int_{R_{i}} d\mathbf{k} \int_{t_{i}}^{t_{i} + \Delta t} dt \frac{A_{i}^{\text{out}}(\mathbf{k}, t)}{\sqrt{R_{i}\Delta t}}$$ \hspace{1cm} (13)

where $R_{i}$ is the region of integration around $k_{i}$ of size $R$, and $\Delta t$ is the time interval [24]. We consider both $R$ and $\Delta t$ independent of $i$. The index $i$ represents different space-time points.

Using the commutation relation of the field outside the cavity,

$$[A_{i}^{\text{out}}(\mathbf{k}, t), A_{j}^{\text{out} \dagger}(\mathbf{k}', t')]= \delta(\mathbf{k} - \mathbf{k}')\delta(t - t'),$$ \hspace{1cm} (14)

it is easy to see that the annihilation and creation operators satisfy $[a_{i}, a_{j}^{\dagger}] = \delta_{i,j}$, where in our notation $i = j$ implies $k_{i} = k_{j}$ and $t_{i} = t_{j}$.

The definition of the $g_{2}$ function in terms of the creation and annihilation operators of the signal field outside the cavity is,

$$g_{2}(k_{i}, t_{i}, k_{j}, t_{j}) = \frac{\langle \tilde{a}_{i}\tilde{a}_{j}\rangle}{\langle \tilde{a}_{i}\rangle\langle \tilde{a}_{j}\rangle},$$ \hspace{1cm} (15)

where $\langle \cdot \rangle$ represents time and normal ordering. We need to express $g_{2}$ in terms of the symmetrically ordered averages that can be obtained numerically. We briefly describe this process in the following.

First, we write $g_{2}$ in terms of continuous operators $A_{i}^{\text{out}}(\mathbf{k}, t)$ using Eq. (13). We use the commutation relation for the outside cavity field (14) to transform normally ordered averages into symmetrically ordered averages. For example, for the term in the denominator of Eq. (15), we have,

$$\langle \tilde{a}_{i}\rangle = \frac{1}{R_{i}\Delta t} \int_{R_{i}} d\mathbf{k} \int_{t_{i}}^{t_{i} + \Delta t} dt \langle \tilde{a}_{i}\rangle$$

$$= \frac{1}{R_{i}\Delta t} \int_{R_{i}} d\mathbf{k} \int_{t_{i}}^{t_{i} + \Delta t} dt \int_{R_{i}} d\mathbf{k}' \int_{t_{i}}^{t_{i} + \Delta t} dt' \langle \tilde{a}_{i}\rangle \langle \tilde{a}_{i}\rangle$$ \hspace{1cm} (16)

We can now replace the symmetrically ordered averages by the averages of the numerically calculated c-number fields, $\alpha_{i}^{\text{out}}(\mathbf{k}, t)$. Considering that the integration region is small, we can use the approximation $\int_{R_{i}} d\mathbf{k} \int_{t_{i}}^{t_{i} + \Delta t} dt \alpha_{i}^{\text{out}}(\mathbf{k}, t) \simeq R_{i}\Delta t \alpha_{i}^{\text{out}}(\mathbf{k}_{i}, t_{i})$, and

$$\langle \tilde{a}_{i}\rangle = R_{i}\Delta t|\alpha_{i}^{\text{out}}(\mathbf{k}_{i}, t_{i})|^{2} - 1/2.$$ \hspace{1cm} (17)

After these steps we find that Eq. (15) can be rewritten as,

$$g_{2}(k_{i}, t_{i}, k_{j}, t_{j}) = \frac{\langle \alpha_{i}^{\text{out}}(k_{i})\alpha_{j}^{\text{out} \dagger}(k_{j})\rangle - (\langle \alpha_{i}^{\text{out}}(k_{i})\rangle + \langle \alpha_{j}^{\text{out} \dagger}(k_{j})\rangle) (1 + \delta_{i,j})}{(\langle \alpha_{i}^{\text{out}}(k_{i})\rangle^{2} - 1/2)(\langle \alpha_{j}^{\text{out} \dagger}(k_{j})\rangle^{2} - 1/2)}$$

where we use the dimensionless quantity $\alpha_{i,j}^{\text{out}} = \sqrt{R_{i}\Delta t\alpha_{i}^{\text{out}}(k_{i}, t_{i})}$ to simplify the notation. Note that if the statistics of $\alpha_{i,j}^{\text{out}}$ and $\alpha_{j}^{\text{out} \dagger,j}$ were independent then $g_{2}(k_{i}, t_{i}, k_{j}, t_{j}) = 1$, therefore a value of $g_{2}$ larger (smaller) than 1 indicates
a positive correlation (anticorrelation) between $\alpha_{ij}^{uu}$ and $\alpha_{ij}^{uu}$. For equal time and position the expression reduces to,

$$g_2(k_i, t_i, k_i, t_i) = \frac{\langle |\alpha_{ij}^{uu}|^4 \rangle - 2\langle |\alpha_{ij}^{uu}|^2 \rangle + 1/2}{\langle |\alpha_{ij}^{uu}|^2 \rangle - 1/2}$$  \hfill (19)

4 Results for the continuous model

We study the degenerate OPO described by Eqs. (5)-(6) close to the instability that produces a square pattern. In the numerical calculations we use the parameters $\Delta_0 = -4$, $\Delta_1 = -2$, $\eta_{ph} = 10^5/\alpha_1$, $2\alpha_0 = \alpha_1$ and $\gamma_1 = \gamma_0$. Space and time are scaled with the values of $\alpha_1$ and $\gamma_1$ respectively in order to use dimensionless quantities. The numerical method of integration that we used involves a spectral integration of the diffraction part and a second order Runge-Kutta method for the rest of the equation [3].

The pump has a radially symmetric shape

$$E_{in}(r) = E_{in}^0 \left[ 1 + \tanh \left( \frac{r_0 - r}{w} \right) \right] / 2$$

where $r = |k|$. This expression yields a large central region with a quite flat profile which decays at $r = r_0$ with a decay rate determined by $w$. This avoids periodic boundary condition effects. We took $r_0 = 65.5$ which is about 14.75 times the critical wavelength for pattern formation and $w = 0.667$. We define the dimensionless pump maximum amplitude as

$$\tilde{E}_{in} = \frac{E_{in}^0}{\sqrt{\eta_{ph}}}$$

Figure 1 shows an intracavity field snapshot just below threshold, for a dimensionless input field value of $\tilde{E}_{in} = 4.119 = 0.999\tilde{E}_{thr}$. In the near field a disordered fractal pattern appears in the signal field while the intracavity pump field remains practically identical to the input pump (notice the different scales given in the figure caption). The ring in the far field of the signal has a radius equal to the wave number that becomes critical above threshold. We calculate the correlation of the fluctuations of the signal modes on this critical ring. We chose a signal mode with a given $k_i$ over the ring, at a time $t_i$, and calculate the correlation with any other signal mode with wavevector $k_j$ over the ring, at time $t_j$. The correlation function $g_2$ is then a function of the angle between $k_i$ and $k_j$ and the time difference $t_d = t_j - t_i$.

In Figure 2 we plot the $g_2$ output field correlation function against the dimensionless scaled time $\gamma_1 t_d$ and the angle. Note that, as discussed in Sect. 3, a value of $g_2 = 1$ corresponds to the uncorrelated case and what is relevant is the deviation of $g_2$ from $g_2 = 1$. There are strong correlations at angles $0$ and $\pi$ which decay exponentially with the time difference and practically no correlation at any other angle. A cut of Figure 2 for zero time difference is shown in Figure 3 where again the $0$ and $\pi$ correlations are seen while for the rest of the angles $g_2 \approx 1$. The correlation at angle $0$ corresponds to the signal far field mode self-correlation while the one at angle $\pi$ corresponds to the correlation between signal modes with opposite wave vector. The correlation at angle $\pi$, also visible in the far field of the signal in Figure 1, is also found when a stripe pattern is formed. It can be understood from the linearized equations in a similar way as in [3] and in [26,10] for a Kerr cavity. Assuming a homogeneous constant pump field $E_{in}$ and linearizing Eq. (6) around the homogeneous solution (10) we obtain in Fourier space,

$$\frac{\partial \alpha_1(k, t)}{\partial t} = -\gamma_1 (1 + i \Delta_1 + i a_1 k^2) \alpha_1(k, t) + g a_0 \alpha_1^*(\mathbf{-k}, t) + \sqrt{2 \gamma_1} \xi (k, t)$$ \hfill (20)

This equation shows a linear coupling between the amplitude of the signal field $\alpha_1(k)$ with the amplitude with opposite wave-vector $\alpha_1(\mathbf{-k})$. The coupling comes from a term that breaks the phase invariance of the equation for $\alpha_1$ and its strength is proportional to the homogeneous component of the pump field which always takes a large value. This linear coupling originates strong correlations in the intracavity signal modes with opposite wave-vectors which are the responsible for the output field correlations measured by the function $g_2$ at angle $\pi$. Therefore the origin of the correlations between signal modes with opposite wave-number can be traced back to the symmetry breaking originated by the pump field. The $\pi$ angle correlations are present both below and above threshold. In the case below threshold, it can be observed even for pump values quite below threshold since the symmetry breaking originated by the pump is always present.

The $\pi$-angle correlation can be interpreted as an effect of transverse momentum conservation in the parametric down-conversion process. When a pump photon with frequency $2\omega$ interacts with the nonlinear medium and the parametric down conversion is produced, two signal photons with frequency $\omega$ are generated. The two emitted photons have opposite transverse wave-vectors due to momentum conservation.

Figure 4 shows a snapshot of the signal field above threshold for pattern formation $E_{in} = 4.2 \approx 1.02 \tilde{E}_{thr}$, in the near and far field. A nice square pattern is formed in the region of the transverse plane where the pump is above threshold. The form of the pattern implies the presence of correlations between signal modes with wave vectors forming an angle of $\pi/2$. The presence of such correlation below threshold would give us information about the kind of pattern that is formed above threshold. Eq. (20) does not show any coupling between the signal modes with wave-vectors forming a $\pi/2$ angle but indicating that there is no linear coupling between these modes. Therefore below threshold correlations at a $\pi/2$ angle could only come from nonlinear interactions, and therefore could be seen only very close to threshold. The numerical simulations at $0.999$ the threshold value do not show any correlation at $\pi/2$ that can be distinguished within our numerical accuracy (see Figs. 2 and 3). Typically this is a value close enough to threshold to see the correlations originated by
nonlinear critical fluctuations [26]. We will analyze the π/2 angle correlations in more detail in the next section in the context of a model in which the form of the pattern is assumed a priori.

5 The 4 modes model

Let us consider the system above and close to the threshold for square pattern formation. The signal field is projected onto 4 spatial modes forming a square approximating it by

$$\alpha_1 = A_1 e^{ik_x x} + A_2 e^{-ik_x x} + A_3 e^{ik_y y} + A_4 e^{-ik_y y}, \quad (21)$$

where \( k_c \) is the critical wave number of the instability (we have chosen the coordinate axis oriented along the square modes).

Due to the term \( \alpha_0^2 \) in Eq. (5), the modes \( \pm k_c, 0 \), \( 0, \pm k_c \), and \( \pm k_c, \pm k_c \) of \( \alpha_0 \) will be excited, so that

$$\begin{align*}
\alpha_0 &= B_0 + B_1 e^{i2k_c x} + B_2 e^{-i2k_c x} + B_3 e^{i2k_c y} + B_4 e^{-i2k_c y} \\
&+ B_5 e^{i(k_c x+y)} + B_6 e^{-i(k_c x+y)} + B_7 e^{i(-k_c x-y)} + B_8 e^{-i(-k_c x-y)},
\end{align*} \quad (22)$$

with \( |B_i| \ll |B_0| \) for \( i = 1 \ldots 8 \). The homogeneous mode \( B_0 \) is much larger than the \( B_i \) modes because it is related to the input pump field, while the \( B_i \) modes are related to the pattern modes \( A_i \) that, close to threshold, should be small.

A system of 13 equations is obtained by replacing Eqs. (21) and (22) in Eqs. (5)-(6). The equations corresponding to the signal modes are,

$$\begin{align*}
\frac{\partial A_1}{\partial t} &= -\gamma_1 (1 + i \Delta_1 + i \alpha_1 k_c^2) A_1 + g(B_0 A_2^* + B_1 A_3^* + B_5 A_3^* + B_7 A_1^*) + \sqrt{2 \gamma_1} \xi_{1,1} \\
\frac{\partial A_2}{\partial t} &= -\gamma_1 (1 + i \Delta_1 + i \alpha_1 k_c^2) A_2 + g(B_0 A_1^* + B_3 A_3^* + B_5 A_5^* + B_7 A_7^*) + \sqrt{2 \gamma_1} \xi_{1,2} \\
\frac{\partial A_3}{\partial t} &= -\gamma_1 (1 + i \Delta_1 + i \alpha_1 k_c^2) A_3 + g(B_0 A_1^* + B_2 A_5^* + B_6 A_5^* + B_8 A_8^*) + \sqrt{2 \gamma_1} \xi_{1,3} \\
\frac{\partial A_4}{\partial t} &= -\gamma_1 (1 + i \Delta_1 + i \alpha_1 k_c^2) A_4 + g(B_0 A_2^* + B_4 A_8^* + B_6 A_8^* + B_7 A_7^*) + \sqrt{2 \gamma_1} \xi_{1,4} \\
\frac{\partial B_0}{\partial t} &= -\gamma_0 (1 + i \Delta_0) B_0 + E_{in} - g(A_1 A_2 + A_3 A_4) + \sqrt{2 \gamma_0} \xi_{0,0} \\
\frac{\partial B_1}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_1 - g(A_1^2 / 2 + \sqrt{2 \gamma_0} \xi_{0,1}) \\
\frac{\partial B_2}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_2 - g(A_2^2 / 2 + \sqrt{2 \gamma_0} \xi_{0,2})
\end{align*} \quad (23)$$

For the pump modes we have,

$$\begin{align*}
\frac{\partial B_3}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_3 - g(A_3^2 / 2 + \sqrt{2 \gamma_0} \xi_{0,3}) \\
\frac{\partial B_4}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_4 - g(A_4^2 / 2 + \sqrt{2 \gamma_0} \xi_{0,4}) \\
\frac{\partial B_5}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_5 - g(A_1 A_3 + \sqrt{2 \gamma_0} \xi_{0,5}) \\
\frac{\partial B_6}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_6 - g(A_2 A_4 + \sqrt{2 \gamma_0} \xi_{0,6}) \\
\frac{\partial B_7}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_7 - g(A_1 A_4 + \sqrt{2 \gamma_0} \xi_{0,7}) \\
\frac{\partial B_8}{\partial t} &= -\gamma_0 (1 + i \Delta_0 + i \alpha_0 k_c^2) B_8 - g(A_2 A_3 + \sqrt{2 \gamma_0} \xi_{0,8})
\end{align*} \quad (24)$$

where \( \xi_{i,j} \) represent the Gaussian noise terms with correlations,

$$\langle \xi_{i,j}(t) \xi_{i',j'}(t') \rangle = \frac{1}{2 L^2} \delta_{i,i'} \delta_{j,j'} \delta(t - t')$$

where \( L \) is the transverse size of the system.

Eqs. (23) and (24) are the minimal model to describe square patterns. Note that we can not neglect the second harmonic contributions, \( B_i \) (\( i = 1 \ldots 8 \)), despite its small amplitude in comparison with \( B_0 \), because these modes play an important role in the couplings above threshold. As shown in eq. (23) they are responsible for the coupling between signal modes with wave vectors forming a π/2 angle. Therefore 13 is the minimum number of equations that we need to take into account.

5.1 Correlations above threshold

We first address the correlations above threshold given by the 4 modes model. We integrate numerically the nonlinear eqs. (23) and (24), including the noise terms, for a pump value 2% above threshold. Figure 5 (a) shows the numerical results for the correlation function between two signal modes with critical opposite wave vectors and with critical wave vectors forming a π/2 angle as function of the time difference \( t_i \). There are strong positive correlations at angle π, as obtained from the continuous model which decay exponentially with the time difference. There is also an anticorrelation between the modes with wave vectors forming a π/2 angle.

These correlations can be understood from the linearized equations for the fluctuations around the steady state solution above threshold, \( A_{i,s} \neq 0 \) and \( B_{i,s} \neq 0 \), which can be obtained finding the stationary solution of the set of Eqs. (23) and (24). This leads to a system of 13 coupled algebraic nonlinear equations that can be solved numerically. Linearizing around this solution we have for the signal modes,

$$\begin{align*}
\frac{\partial \delta A_1}{\partial t} &= -\gamma_1 (1 + i \Delta_1 + i \alpha_1 k_c^2) \delta A_1 + g(B_0, \delta A_2^* + A_2, \delta B_0 \\
&+ B_1, \delta A_3^* + A_3, \delta B_1 + B_5, \delta A_3^* + A_3, \delta B_5 \\
&+ B_7, \delta A_7^* + A_7, \delta B_7) + \sqrt{2 \gamma_1} \xi_{1,1}
\end{align*} \quad (25)$$
\[
\frac{\partial \delta A_2}{\partial t} = -\gamma_l (1 + i \Delta_1 + ia_1 k_2^2) \delta A_2 + g(B_0, \delta A'_1 + A_1', \delta B_0 + B_2, \delta A'_2 + A_2', \delta B_3 + B_5, \delta A'_3 + A_3', \delta B_7 + B_8, \delta A'_4 + A_4', \delta B_8) + \sqrt{2\gamma_l,}
\]

\[
\frac{\partial \delta A_3}{\partial t} = -\gamma_l (1 + i \Delta_1 + ia_1 k_2^2) \delta A_3 + g(B_0, \delta A'_1 + A_1', \delta B_0 + B_5, \delta A'_2 + A_2', \delta B_7 + B_8) + \sqrt{2\gamma_l,}
\]

\[
\frac{\partial A_4}{\partial t} = -\gamma_l (1 + i \Delta_1 + ia_1 k_2^2) A_4 + g(B_0, \delta A'_1 + A_1', \delta B_0 + \delta A'_2 + A_2', \delta B_7 + \delta B_8) + \sqrt{2\gamma_l,}
\]

This set of equations shows a linear coupling between the fluctuations of modes separated by an angle \(\pi\), such as \(\delta A_1\) and \(\delta A_2\) or \(\delta A_3\) and \(\delta A_4\), and by an angle \(\pi/2\) such as for example between \(\delta A_1\) and \(\delta A_2\) or \(\delta A_3\) and \(\delta A_4\). In the first case the strength of the coupling is proportional to the homogeneous component of the intracavity pump field \(B_{0,s}\), while the \(\pi/2\) angle coupling is mediated by the stationary values of the pump field pattern modes \(B_{0,s}\) \((i = 1, ..., 8)\). This linear coupling will imply significantly large correlations between the signal output field modes with wave vectors forming a \(\pi\) and a \(\pi/2\) angle as obtained numerically from the nonlinear equations (23)-(24) and shown in Fig. 5.

An alternative way to explain the correlation above threshold between the output signal far field modes forming an angle \(\pi/2\) can be obtained from the energy expression we derived at the end of Sect. 2. As above threshold the square pattern is fully developed, we can approximate \(|A_1| \approx |A_2|\) and \(|A_3| \approx |A_4|\), so,

\[
\alpha_1 = A_1 \cos(k_x x + \phi_x) + A_2 \cos(k_y y + \phi_y).
\]

Replacing Eqs. (26) and (22) in Eq. (12), we get,

\[
P = 2\hbar \omega L^2 [2 \Re(E_{in}B_0^* - 2 \Re(B_0^2) - \gamma_l (|A_1|^2 + |A_2|^2)],
\]

where \(L\) is the transverse size of the system, and we have neglected terms of order \(B_i B_j\) with \(i, j = 1, ..., 8\). Since in a steady state \(P\) have small fluctuations around zero, the fluctuations of the quantities in the r.h.s. of Eq. (27) must cancel. For example, a positive fluctuation of \(|A_1|^2\) can be compensated by a negative fluctuation of \(|A_2|^2\).

We have also calculated the correlation function \(g_2\) at the output between a mode of the signal (\(A_i\)) and the homogeneous mode of the pump (\(B_0\), that we call \(g_2(A_1, t, B_0, t')\). As shown in Fig. 5 there is a small anticorrelation at equal times which quickly decays as the time difference increases. The linearized eqs. (25) show also a coupling between \(\delta A_1\) and \(\delta B_0\) with a strength proportional to \(A_2^2\), which can be considered for this anticorrelation. Likewise, this anticorrelation can be understood from Eq. (27).

5.2 Correlations below threshold

We now address the question of the correlations just below threshold \(\langle \hat{E}_{in} = 4.119 = 0.999 \hat{E}_{thr} \rangle\) given by the 4 modes model (23)-(24). Although the 4-modes model is a good approximation of the continuous model only above and close to threshold, we explore its use to calculate the correlations below threshold. The problem below threshold is that this simplified model represents a truncated version of the continuous model, where the infinite number of modes in the critical circle of the signal far field is reduced to 4.

Figure 6 (a) shows the numerical results for the correlation function between two signal modes with critical opposite wave vectors and with critical wave vectors forming a \(\pi/2\) angle as function of the time difference \(\tau_d\). As in the case above threshold, there are strong positive correlations at angle \(\pi\), as obtained from the continuous model, which decay exponentially with the time difference. The new result is that there is also an anticorrelation between the modes with wave vectors forming a \(\pi/2\) angle.

The steady state solution below threshold is \(A_{0,s} = 0\) \((i = 1, ..., 4)\), \(B_{0,s} = 0\) \((i = 1, ..., 8)\), and only \(B_{0,s}\) is different from zero. If we linearize around this solution we get, for the signal modes,

\[
\frac{\partial \delta A_1}{\partial t} = -\gamma_l (1 + i \Delta_1 + ia_1 k_2^2) \delta A_1 + g(B_0, \delta A'_1 + A_1', \delta B_0 + B_5, \delta A'_2 + A_2', \delta B_7 + B_8) + \sqrt{2\gamma_l},
\]

\[
\frac{\partial \delta A_2}{\partial t} = -\gamma_l (1 + i \Delta_1 + ia_1 k_2^2) \delta A_2 + g(B_0, \delta A'_1 + A_1', \delta B_0 + \delta A'_2 + A_2', \delta B_7 + \delta B_8) + \sqrt{2\gamma_l},
\]

\[
\frac{\partial \delta A_3}{\partial t} = -\gamma_l (1 + i \Delta_1 + ia_1 k_2^2) \delta A_3 + g(B_0, \delta A'_1 + A_1', \delta B_0 + B_5, \delta A'_2 + A_2', \delta B_7 + B_8) + \sqrt{2\gamma_l},
\]

which shows the presence of linear couplings between the amplitude of the fluctuations of modes with opposite wave vectors: \(\delta A_1\) and \(\delta A_2\) or \(\delta A_3\) and \(\delta A_4\). As in the linearized continuous model (20) discussed in the previous section, the strength of the coupling is proportional to the homogeneous mode \(B_{0,s}\), which is always strong. This linear coupling is responsible for the strong correlation found in the \(g_2\) function between output signal modes and opposite wave vector. Also, as in the continuous model there is no coupling, in the linearized equations, between the fluctuations of signal modes with wave vectors forming a \(\pi/2\) angle. Above threshold this coupling was proportional to the amplitude of the pump pattern modes, which is zero below threshold. The \(\pi/2\) angle correlations come from nonlinear interactions, and therefore can be seen only very close to threshold. In fact we see them here because we are just at 0.1% below threshold. This result is due to the mode truncation and disappears moving further below threshold and in the continuous limit. For example, if we consider an input field of \(\hat{E}_{in} = 0.9 \hat{E}_{thr}\), the correlations at angle \(\pi\) remain strong while the nonlinear correlations at \(\pi/2\) vanish as shown in Fig. 7 (a).

Finally we show in Fig. 6 the correlation \(g_2(A_1, t, B_0, t')\) between the \(A_1\) mode of the signal, and the homogeneous
pump mode $B_0$. As in the case above threshold there is a small anticorrelation at equal times which quickly decays as the time difference increases. Again there is no coupling in the linearized equations (28) between the signal mode and the pump mode fluctuations, so this correlation comes from nonlinear interactions and it can be observed only very close to threshold. As shown in Fig. 7 this correlation vanishes for pump $\bar{E}_{in} = 0.9\bar{E}_{thr}$.

A final remark is that the correlations measured through the function $g_2$ just below threshold, can be stronger than the ones above threshold (compare Figs. 6 with 5). This occurs even in the case of the $\pi/2$ correlation which just below threshold appears only due to nonlinear effects while above threshold is generated by linear couplings. This result can be understood taking into account the fact that the $g_2$ function is normalized with the mode intensities and the average intensity of the modes just below threshold is much smaller than above it.

6 Final discussion and conclusion

We found three types of quantum correlations close to an instability for square pattern formation in degenerate optical parametric oscillators. First, a strong correlation between opposite wave-vector modes of the signal far field. It is clearly present in both the continuous and the 4 modes model and it can be understood as an effect of momentum conservation in the parametric down conversion process of one pump photon into two signal photons (twin photon emission). Alternatively its origin can be related to the phase symmetry breaking induced by the pump field similar to what is obtained for a Kerr cavity [26]. The coupling between opposite wave-vector signal modes already appears in the linearized equations around the steady state, both below and above threshold and therefore this correlation appear either above or below threshold, and not necessarily close to it. Quantum aspects of this correlation were already studied, specially in the case of a stripe pattern formation [4, 25, 3], and more recently in spatially disordered structures [18].

Second, above threshold, we find anticorrelation between the signal field modes with critical wave vectors forming an angle of $\pi/2$. This correlation can be explained from the linearized equations above threshold which show a direct coupling between the fluctuations of these modes. Below threshold the amplitude of the pump field pattern modes is zero and therefore in the linearized equations there is no coupling between the fluctuations of the signal modes with wave vectors forming a $\pi/2$ angle. In fact, pattern selection is a nonlinear process, and the question of which pattern is selected cannot be answered by a linear analysis. Despite that, using the nonlinear 4 modes model, one finds correlations between these modes for pump values extremely close to threshold ($\bar{E}_{in} = 0.99\bar{E}_{thr}$) which come from the nonlinearities and are a manifestation of critical fluctuations. These correlations quickly vanish with decreasing the pump value. In the continuous model, however, we found numerically no correlations between the signal modes emitted with wave vectors forming a $\pi/2$ angle even extremely close to threshold ($\bar{E}_{in} = 0.99\bar{E}_{thr}$).

The statistics we have for the continuous model involve 11400 samples and therefore the numerical result for the $g_2$ correlation has a limited precision. The result we obtain for the correlation function $g_2$ differs from 1.00 (uncorrelated case) in less than 0.03 which is within the limits of the statistics. This is significantly different from the value $g_2 = 0.92$ obtained from the 4 mode model at the same pump level. We believe that the $\pi/2$ correlations obtained from the 4 mode model are over-magnified by the reduction of the number of critical modes to 4 in the signal field instead of considering the continuous ring of critical modes $|k| = k_c$. Therefore, we can not say that the correlations between the fluctuations below threshold do carry any information about the specific square form of the pattern that arises above threshold. They are a noisy precursor of the pattern in the sense that they tell us about the critical wave number of the pattern but they are not a quantum image of the pattern that shows what kind of pattern is formed above threshold.

We also find an anticorrelation between the homogeneous pump mode and any of the critical signal modes. Numerical results of the 4-modes model shows that it is present above or below threshold. A similar anticorrelation has been found in a Kerr medium [26]. Here it can be explained by considering that a positive fluctuation of the intracavity pump field means that there are less photons than average that are parametrically down converted, and so, less signal photons are produced. Above threshold this anticorrelation comes from linear coupling in the linearized equations. Below threshold it is a manifestation of non-linear critical fluctuations, and therefore it can be observed only very close to threshold.

Finally, we note that our results are based on the numerical evaluation of the second-order coherence function $g_2$. The use of this function in the characterization of quantum properties of spatially extended nonlinear optical systems is far more general than the specific case of square patterns studied here. The evaluation of the $g_2$ function and a comparison with experimental result can be beneficial when studying, for example, quantum correlations between fluctuations around spatially localized features such as domain walls and dark ring cavity solitons [23].

7 Acknowledgments

We want to acknowledge essential discussions for the accomplishment of this work with S.M. Barnett, A. Gatti and L.A. Lugliato. This work is supported by the European Commission through the TMR network QSTRUCT (FMRX-CT96-0077) and through the project QUANTIM (IST-2000-26019) and from the MCyT (Spain, Projects PB97-0141-C02-02 and BFMB2000-1108). A Numerical calculation of $\alpha_i^{out}$

The space-time evolution of $\alpha_i^{out}$ and $\alpha_i^{out}$ can be obtained numerically using the method presented in [10]. We write Eqs. (5)-(6) for the intracavity fields as, $\frac{d\alpha_i}{dt} = f_i(\alpha_0, \alpha_1) + \sqrt{2\gamma_i} \xi_i$, where the index $i$ is 0 or 1. We consider a discretized time $t = n\tau$, where $\tau$ is a small time step and $n$ is an integer. At time $n\tau + s$ we have,

$$\alpha_i(n\tau + s) \approx \alpha_i(n\tau) + f_i(n\tau) s + \sqrt{2\gamma_i} \int_{n\tau}^{n\tau + s} \xi_i(t) dt \quad (29)$$

The average value of $\alpha_i$ in the time interval $n\tau \rightarrow n\tau + \tau$ is,

$$\alpha_{i,n} = \frac{1}{\tau} \int_0^{\tau} \alpha_i(n\tau + s) ds$$

$$\approx \alpha_i(n\tau) + \frac{f_i(n\tau)}{2} \frac{\tau}{\tau} + \sqrt{\gamma_i} \int_0^{\tau} ds \int_{n\tau}^{n\tau + \tau} \xi_i(t) dt$$

$$\approx \frac{\alpha_i(n\tau) + \alpha_i(n\tau + \tau)}{2} - \xi_i + \xi_{i,n} \quad (30)$$

The dependence of $\xi_i$ is not explicitly written to simplify the notation. Using the input-output relation $\alpha_i^{out} = \sqrt{2\gamma_i} \alpha_i - (\xi_i + \xi_{i,n})$, where $\xi_{0,n} = E_{in}/\sqrt{2\gamma_0}$ and $\alpha_1 = 0$, and Eq. (30) we get the average value of the output field at time step $n\tau$,

$$\alpha_{i,n}^{out} = \frac{1}{\tau} \int_0^{\tau} \alpha_{i,n}^{out}(n\tau + s) ds$$

$$= \frac{\sqrt{2\gamma_i}}{\tau} \alpha_i(n\tau) + \frac{\alpha_i(n\tau + \tau)}{2} - \xi_i + \xi_{i,n} \quad (31)$$

where $\xi_{i,n}$ is the noise of the output field at time step $n\tau$; it is related to the input noise $\xi_i$ via the equation,

$$\xi_{i,n} = \frac{2\gamma_i}{\tau} \int_0^{\tau} ds \int_{n\tau}^{n\tau + \tau} \xi_i(s') ds - \frac{1 + \gamma_i \tau}{\tau} \int_{n\tau}^{n\tau + \tau} \xi_i(s) ds \quad (32)$$

The previous equations hold for both near field and far field, since they are linear. The correlations of $\xi_i$ in the far field, are,

$$\langle \xi_{i,n}(k) \xi_{i',n}(k') \rangle = \frac{1}{2\tau} \left( \frac{\gamma_i}{3} \tau^2 + 1 \right) \delta_{nn'} \delta(k - k')$$

$$\langle \xi_{i,n}(k) \xi_{i,n}(k') \rangle = \frac{1}{2\tau} \delta_{nn'} \delta(k - k') \quad (33)$$

where $\xi_{i,n}(k) = \frac{1}{\tau} \int_{n\tau}^{n\tau + \tau} \xi_i(k, t) dt$. The correlations are fulfilled if we relate $\xi_{i,n}$ to $\xi_{i,n}$ as,

$$\xi_{i,n}(k) = -\xi_{i,n}(k) + \sqrt{\gamma_i} \sigma_i(k) \quad (35)$$

where $\sigma_i(k)$ is an independent Gaussian noise with $\langle \sigma_i(k) \sigma_i'(k') \rangle = \frac{\gamma_i}{2\tau} \delta(k - k')$. In the numerical simulations we used $\tau$ equal to the time step of the integration scheme.
