26 **Abstract**

27 Peripheral blood from healthy sheep ($n=3$) and goats ($n=3$) were employed to establish an
28 efficient method for simultaneous isolation of peripheral blood mononuclear cells (PBMCs) and
29 neutrophils and to standardize protocols for monocyte purification and generation of monocyte-
30 derived macrophages (MDMs). In both species, a significantly enriched population of PBMCs,
31 with higher purity and number of cells determined by flow cytometry, was achieved when
32 processing through a density gradient a mixture of buffy-coat and red blood cell layer (RBC) in
33 comparison to the use of just the buffy-coat ($p < 0.05$). Neutrophils could be subsequently
34 isolated from the layer, located underneath PBMCs fraction with significant higher purity rates,
35 higher than 85% determined by flow cytometry, than those obtained with protocols without
36 density gradients ($< 60\%$) ($p < 0.05$). This technique would allow the isolation of both cell
37 populations from the same sample of blood. A pure cell population of monocytes, CD14⁺ cells,
38 was purified from PBMCs when using immunomagnetic columns, which allow for 17% (n°
39 monocytes/ n° PBMCs) of yield and high percentages of expression of CD14⁺ (88%), MHC-II⁺
40 (91.5%) and CD11b⁺ (94%) established by flow cytometry. On the other hand, the classical and
41 non-expensive purification of monocytes from PBMCs based on the adherence capacity of the
42 former, allowed significantly lower yield of monocytes (4.6%), with percentages of surface
43 markers expression that dropped to 35%, 65% and 55%, respectively ($p < 0.001$), suggesting
44 the isolation of a mixed population of cells. The addition of GM-CSF to the culture, at
45 concentration from 25 to 125 ng/ml, enhanced proportionally the number of MDMs generated
46 compared to the absence of supplementation or the use of autologous serum from 5% to 20%.
47 However, purification of monocytes through the adherence method achieved higher yields of
48 MDMs than those isolated through immunomagnetic columns in both species ($p < 0.001$).
49 Under the conditions of this study, the use of centrifugation in density gradients allow for the
50 simultaneous purification of PBMCs and neutrophils, with high purity of both populations, from
51 the same sample of blood. The isolation of monocytes could be subsequently achieved through
52 two different methods, i.e. based on immunomagnetic columns or adherence. The preference

53 between both methods would depend on the necessities of the experiment, the initial sample
54 with high purity of monocytes or a final population of MDMs required.

56 *Keywords:* PBMCs; neutrophils; monocytes; monocyte-derived macrophages; sheep; goats.

58 *Abbreviations:* AICc, Akaike's Information Criterion; BSA, bovine serum albumin; FBS,
59 fetal bovine serum; FITC, fluorescein isothiocyanate; FSC, forward scatter; GLMs, generalized
60 linear models; GM-CSF, granulocyte macrophage colony-stimulating factor; LM, linear model;
61 MDMs, monocyte-derived macrophages; PBMCs, peripheral blood mononuclear cells; RBC,
62 red blood cell; SCC, side scatter.

64 **1. Introduction**

65 Macrophages and neutrophils play a crucial role in the innate immune response
66 defending the host from pathogens and maintaining homeostasis, although they also take part in
67 the adaptive immune response priming other immune host cells for enhanced microbicidal
68 activity (Gordon and Taylor, 2005; Borregaard et al., 2007). Due to their biological function,
69 their study is the key for a greater understanding of the host-pathogen interaction, particularly in
70 those caused by intracellular pathogens. Cell culture allows the study of the response of these
71 cells after their contact with the pathogen (expression and production of cytokines, phagocytosis
72 or microbicidal activity) (Borrmann et al., 2011; Elmowalid et al., 2013). In human research,
73 there is a well standardized methodology for the *in vitro* culture of these cells. In contrast, in
74 veterinary research, and especially in small ruminants, there is lack of a common agreement
75 with respect to the development of an effective method for the isolation and culture of
76 monocytes, macrophages and neutrophils.

77 Since the isolation of mature macrophages from tissues is labour-intensive and
78 ineffective, the generation of monocyte-derived macrophages (MDMs) from blood monocytes is
79 the most feasible approach to obtain these immune cells (Daigneault et al., 2010). Blood
80 monocytes are present within the mononuclear cells fraction of the peripheral blood. To isolate

81 this fraction, the use of density gradients, including a variety of chemical compounds such as
82 Percoll®, Histopaque®, Ficoll-Paque™ or Lymphoprep™ is the most well-known and
83 employed method in ruminants following different protocols (Olivier et al., 2001; Keane et al.,
84 2002; Souza, 2015). Commonly, once peripheral blood mononuclear cells (PBMCs) are
85 isolated, monocytes are purified based on their property of adhesion on plastic surfaces and
86 subsequent elimination of non-adherent cells by washing culture plates (Olivier et al., 2001;
87 Berg et al., 2013; Elmowalid et al., 2013). However, the use of immunomagnetic columns and
88 specific anti-human antibodies coupled with magnetic beads has become a common procedure
89 in human research for a fast and efficient isolation of various cell populations such as peripheral
90 blood monocytes (Nakazawa et al., 2016; Nielsen et al., 2020). In this sense, the proved
91 existence of cross-reaction of these antibodies with antigens of ruminant monocytes has also
92 allowed its use with apparently optimal results in cattle and sheep (Budhia et al., 2006;
93 Machugh et al., 2012; Souza, 2015).

94 Once purified, *in vitro* culture of monocytes allows the obtaining of MDMs through a
95 maturation process that depends on suitable conditions of culture and permits their use as a
96 model for the study of macrophages (Daigneault et al., 2010; Elmowalid, 2012). In this sense,
97 the influence of serum and/or different growth factors on the maturation and polarization of
98 MDMs are well-established in human research (Eske et al., 2009; Ambarus et al., 2012; Vogel
99 et al., 2014). However, this maturation has been carried out in ruminants using specific culture
100 media supplemented with fetal bovine serum (FBS) or autologous serum (Werling et al., 2004;
101 Gollnick et al., 2007; Elmowalid, 2012) together with the addition of granulocyte macrophage
102 colony-stimulating factor (GM-CSF) to supplemented media (Budhia et al., 2006; Souza, 2015;
103 Pomeroy et al., 2016; García-Sánchez et al., 2019). Nevertheless, the optimal concentrations of
104 GM-CSF are unclear and vary from 4 ng/ml to 100 ng/ml in these studies. All these studies state
105 that MDMs are suitable for subsequent functional studies, however, there are no evidences that
106 determine which of these culture conditions are the most appropriate to gain the largest number
107 of MDMs, especially in sheep and goats.

108 Neutrophils are also an important cell population that actively participates in the host
109 immune response. As in the case of MDMs, their study under *in vitro* conditions allows the
110 knowledge about mechanisms of the host immune response under tightly controlled conditions
111 (Borregaard, 2010). While in human research there are standardized protocols for the isolation
112 of neutrophils (Siemsen et al., 2014), different methods have been proposed for their isolation
113 from peripheral blood in ruminants, most of them based on the direct lysis of erythrocytes
114 (Paltrinieri et al., 2000; Hellenbrand et al., 2013; Jimbo et al., 2017) and few of them based on
115 the centrifugation of blood with density gradients compounds (Silva et al., 2014; Cacciotto et
116 al., 2016). The purity and quality of the isolated neutrophils in ruminants are generally assessed
117 by direct microscopic visual evaluation and/or analysis of the size and granularity of the cells
118 through flow cytometry (Carretta et al., 2013; Zoldan et al., 2014; Kamoshida et al., 2015),
119 obtaining similar and optimum results despite the wide range of available protocols.

120 Despite the great variety of protocols for the isolation of neutrophils and monocytes
121 employed in different ruminant species (mainly cattle), their use in small ruminants (sheep and
122 goats) is scarce and the fewer published studies show important differences on the methodology
123 (Elmowalid, 2012; Siemsen et al., 2014; Silva et al., 2014). In this sense, an agreed protocol for
124 their isolation would help to make comparable all the studies carried out in these ruminant
125 species. Thus, due to the importance of these cell populations, the main objective of this study is
126 to establish a suitable and effective procedure for PBMCs and neutrophil isolation from the
127 same blood sample in sheep and goats as well as establish the best procedure for the purification
128 of monocytes from PBMCs and the subsequent generation of MDMs exploring and comparing
129 different technical protocols.

130

131 **2. Material and Methods**

132 *2.1. Animals*

133 This study was carried out using healthy, non-pregnant, one year old sheep ($n = 3$) and
134 goats ($n = 3$) of assaf and murciano-granadina breeds respectively, belonging to the

135 experimental herd of the Instituto de Ganadería de Montaña (ULE-CSIC) in Grulleros, León,
136 Spain. All the procedures have been designed according to European (86/609) and Spanish laws
137 (R.D. 223/1988, R.D. 1021/2005 and R.D. 53/2013). Handling and sampling procedures were
138 minimized in order to reduce stress and health risks for the animals and staff involved. A blood
139 sample (200 ml) was collected from each animal twice a month to reduce stress and allow their
140 recovery. Then, three technical replicates were performed from each animal to carry out all the
141 different procedures.

142

143 *2.2. PBMCs isolation*

144 Two different protocols for the isolation of PBMCs were evaluated (Fig. 1):

145

146 *2.2.1. Isolation from buffy-coat*

147 Whole blood samples were collected by jugular venipuncture using 10 ml BD
148 Vacutainer™ tubes with lithium heparin as anticoagulant and PBMCs were isolated from the
149 buffy-coat fraction as previously described Chan et al. (2002) with few modifications (Fig. 1).
150 Briefly, whole blood was centrifuged at 650 x g for 30 minutes at room temperature with no
151 stop or acceleration. The obtained buffy-coat was collected and topped up to 15 ml with
152 PBS/EDTA (2 mM EDTA, pH. 8) to be layered upon 15 ml of Lymphoprep™ (STEMCELL
153 Technologies®, Grenoble, France) and centrifuged at 800 x g for 30 minutes under the same
154 conditions mentioned above. The interphase of mononuclear cells isolated from PBMCs and
155 located between plasma and Lymphoprep™ fractions was aspirated and washed with 30 ml
156 PBS/EDTA by centrifugation at 300 x g for 10 minutes at 4°C. Later on, the cell pellet was
157 resuspended in 3 ml of 0.03% of sodium bicarbonate for the lysis of erythrocytes, shaken for 10
158 seconds and isotonicity was restored adding 40 ml of PBS/EDTA and centrifuged at 300 x g for
159 10 minutes. Then, the cell pellet was washed again with 20 ml of PBS/EDTA and resuspended
160 in 15 ml of RPMI1640 medium+GlutaMAX™ with phenol red (Gibco, ThermoFisher
161 Scientific®) supplemented with 10% of heat-inactivated FBS (Gibco, ThermoFisher Scientific®),

162 1% of penicillin/streptomycin/amphotericin (Santa Cruz Biotechnology®) and 50 µM of 2-β-
163 Mercaptoethanol (Gibco, ThermoFisher Scientific®).

164

165 *2.2.2. Isolation from buffy-coat and red blood cell layer*

166 Blood samples were collected as explained above (2.2.1. section) and were diluted at a
167 1:3 proportion in PBS/EDTA (Fig. 1). Diluted blood was centrifuged at 650 x g for 30 minutes
168 at room temperature with no stop or acceleration and the buffy-coat plus the layer of red blood
169 cells (RBC) layer located immediately below were collected, topped up to 15 ml with
170 PBS/EDTA and layered upon Lymphoprep™ (STEMCELL Techonologies®, Grenoble, France).
171 Afterwards, the PBMCs interphase was collected and resuspended as previously mentioned
172 above (2.2.1.).

173

174 *2.2.3. Cell counting and flow cytometry analysis*

175 In order to compare both methods, the number of PBMCs was counted using a
176 Neubauer chamber. Besides, their size and complexity were characterized through the analysis
177 of 10.000 events using a flow cytometer (MACSQuant, MiltenyiBiotec®) and the percentage of
178 PBMCs was estimated using side scatter (size) versus forward scatter (granularity) plots
179 (SCC:FSC), gating the characteristic location of this populations in order to calculate the
180 percentage of purity using the MACSQuantify10 Software™ (MiltenyiBiotec®).

181

182 *2.3. Monocyte purification*

183 Two purification techniques for monocyte purification from PBMCs were assessed
184 using previously isolated PBMCs from the buffy-coat plus RBC layer (method explained at
185 2.2.2. section) due to the favorable results obtained during PBMCs isolation.

186

187 *2.3.1. Purification of monocytes by the adherence method*

188 Monocytes were purified from PBMCs as previously describe Elnaggar et al. (2016) for
189 sheep and goats with few modifications. A total of 1.5×10^7 PBMCs per well were seeded on a

190 six-well culture plate (TPP[®], Sigma-Aldrich) in a final volume of 3 ml RPMI1640
191 supplemented medium mentioned above and were incubated for 3 hours at 37°C and 5% CO₂ in
192 a humidified incubator. Subsequently, non-adherent cells were carefully removed with warm
193 PBS. In order to estimate the number of purified monocytes, plates were placed on ice for 15-20
194 minutes with 3 ml of cold PBS/EDTA and were slightly scraped and recovered by gentle
195 pipetting.

196

197 *2.3.2. Purification of monocytes by immunomagnetic columns*

198 As previously described Budhia et al. (2006) for sheep, a CD14⁺ cell selection was
199 performed from PBMCs using MACS LS columns (MiltenyiBiotec[®]) according to the
200 manufacturer's instructions. Briefly, a total of 2x10⁷ PBMCs were pelleted and resuspended in
201 40 µl solution of microbeads conjugated to monoclonal anti-human CD14 antibody
202 (MiltenyiBiotec[®]), diluted in 160 µl of PBS/EDTA supplemented with 0.05% of bovine serum
203 albumin (BSA) and incubated during 15 minutes at 4°C. Afterwards, PBMCs were washed with
204 4 ml of PBS/EDTA and resuspended in 500 µl of PBS/EDTA/BSA. PBMCs were then loaded
205 onto LS separation column placed in the MACS magnet and a positive selection of CD14⁺ cells
206 was performed, with CD14⁺ cells retained in the column, while the negative cells passed
207 through it. Finally, the column was removed from the magnetic field and 5 ml of RPMI 1640
208 supplemented medium was passed through the column, with the aid of a plunger, to wash, and
209 purify the CD14⁺ cells.

210

211 *2.3.3. Monocyte yield and phenotypic analysis*

212 The quantity and phenotypic characteristics of purified monocytes obtained by both
213 purification techniques were compared. In order to calculate the yield of monocytes obtained
214 though adherence method and immunomagnetic columns, recovered adherent cells and CD14⁺
215 cells, respectively were counted in a Neubauer chamber. The yield of monocytes of each
216 purification techniques was calculated as the percentage of purified monocytes (number of
217 monocytes/ number of initial PBMC*100) in both animal species.

218 Afterwards, the phenotype of the monocytes obtained through both purification
219 techniques was studied using flow cytometry analysis. Briefly, besides the analysis of the size
220 and complexity of the cells, monocytes were labeled using monoclonal antibodies anti-bovine
221 CD14 (clone CC-G33, MCA2678, Bio-Rad[®]) and anti-sheep MHC-II (clone 37.68, MCA2226,
222 Bio-Rad[®]) at a 1:100 dilution, and anti-bovine CD11b (clone CC126, MCA1425, Bio-Rad[®]) at a
223 1:150 dilution for 1 hour at 4°C. Then, cells were washed with PBS and incubated with
224 Fluorescein isothiocyanate (FITC)-conjugated anti-mouse IgG secondary antibody at a 1:50
225 dilution (F0313, Dako[®]) for one 1 hour in darkness at 4°C. Finally, cells were washed again
226 and fixed with 1% BD CellFIX[™]. Sample acquisition of 10.000 events was performed using a
227 flow cytometer (MACSQuant, MiltenyiBiotec[®]) where events were gated during the acquisition
228 analysis (Supplementary Figure 1) to discard the presence of air and doublets. Analysis of data
229 was performed using the MACSQuantify10 Software[™] (MiltenyiBiotec[®]). Results were
230 expressed as percentage of positive cells and mean fluorescence intensity for each cell
231 phenotype (Corripio-Miyar et al., 2015).

232 233 *2.4. Generation of MDMs*

234 *2.4.1. In vitro culture conditions of monocytes*

235 Generation of MDMs was carried out by two different methods by means adding
236 different concentrations of ovine GM-CSF (RP1190V-100, KingFisher Biotech[®], INC) or
237 autologous serum to the supplemented RPMI 1640 culture media in monocytes purified through
238 the adherence method as explained in 2.3.1. section. GM-CSF concentrations of 0 ng/ml, 25
239 ng/ml, 60 ng/ml and 125 ng/ml as well as autologous serum at 5%, 10% and 20%
240 concentrations were employed. Autologous serum was obtained from the same animals used for
241 monocyte isolation, collecting blood by jugular venipuncture into 10 ml BD Vacutainer[™] tubes
242 without anticoagulant and allowed to clot overnight. Afterwards, samples were centrifuged at
243 430 x g, 15 minutes at 4°C and serum was collected and heat-inactivated at 56°C for 30 minutes.

244 Finally, serum was filter-sterilized through 0.2 µm filter (10462200, Biotech®) and aliquoted
245 until use.

246 Supplemented RPMI 1640 media cell culture with GM-CSF or autologous serum was
247 added to each well and changed the third day of culture with fresh media. Each concentration
248 was studied by duplicate. At the seventh day of culture, plates with MDMs were carefully
249 washed twice with 3 ml of warm PBS and harvested by adding and 3 ml of cold PBS/EDTA and
250 placed on ice for 20 minutes. MDMs were then slightly scraped and recovered in 5 ml of
251 RPMI1640 supplemented medium.

252

253 2.4.2. Purification conditions of monocytes

254 To further analyze whether the purification of monocytes through adherence method or
255 immunomagnetic columns could influence the generation of MDMs, in terms of the total
256 number of recovered MDMs and their phenotype, purified monocytes by means of both
257 purification techniques and generated MDMs after 7 days of supplementation with 60 ng/ml of
258 GM-CSF were scraped as mentioned above and recovered in 5 ml of RPMI1640 supplemented
259 medium until use.

260

261 2.4.3. MDM yield and phenotypic analysis

262 The morphological features of MDMs obtained in sections 2.4.1. and 2.4.2. (changes on
263 the size, shape and granularity as well as dimension of cytoplasm) were daily assessed by the
264 examination of the culture plates under inverted microscope (LEITZ DM IL®, Leica), from the
265 first to the seventh day of culture.

266 The number of recovered MDMs with different *in vitro* conditions and the yield of
267 recovered MDMs with different purification techniques was counted with a Neubauer chamber
268 and were estimated as the total number of recovered MDMs.

269 To characterize the phenotype of these MDMs, size, complexity and the expression of
270 different surface markers were analyzed by flow cytometry (MACSQuant, MiltenyiBiotec®).
271 MDMs were labeled using the same antibodies and methodology explained in 2.3.3. section.

272 The percentage of positive cells and fluorescence intensity was recorded and compared between
273 both purification techniques but also between monocytes and MDMs obtained by both
274 purification techniques. Thus, differences between cell type, purification technique and animal
275 species were considered as variables in further analysis.

276

277 *2.5. Neutrophils isolation from peripheral blood*

278 Three different methods for the isolation of neutrophils from peripheral blood were
279 evaluated.

280

281 *2.5.1. Isolation of neutrophils without density gradients*

282 This method is based on previous works carried out in sheep and cattle with slight
283 modifications (Paltrinieri et al., 2000; Hellebrand et al., 2013). Heparinized blood were
284 collected by jugular venipuncture and centrifuged at 400 x g for 20 minutes. The RBC layer just
285 below the buffy-coat, where the neutrophil fraction is present, was collected and diluted in
286 distilled water for erythrocytes lysis in a dilution of 1:3 by gently shaking for 10 seconds. Then,
287 neutrophils were diluted in PBS/EDTA to restore isotonicity, pelleted at 300 x g for 10 minutes
288 and washed with PBS/EDTA four times. Finally, pelleted neutrophils were resuspended in
289 RPMI1640 medium (Gibco, ThermoFisher Scientific®).

290

291 *2.5.2. Isolation of neutrophils using Percoll®*

292 This method is based on previous works conducted in small ruminants with few
293 modifications (Woldehiwet et al., 2003; Siemsen et al., 2014). Heparinized blood samples were
294 centrifuged and the RBC layer was collected as mentioned above. Erythrocytes were lysed using
295 20 ml distilled water, inverting tubes for 20 seconds. The isotonicity was restored by the
296 addition of 20 ml of PBS/EDTA and tubes were centrifuged at 250 x g for 5 minutes at room
297 temperature with low brake. The supernatant was removed and the pellet was washed again with
298 40 ml of PBS/EDTA. Then, the pellet was resuspended with 9 ml of PBS/EDTA, was layered

299 on of 65% of Percoll[®]/EDTA solution in a proportion of 3:5 and was centrifuged at 400 x g for
300 20 minutes with no brake. After centrifugation, the interphase layer was collected and washed
301 twice with 40 ml of PBS/EDTA at 400 x g for 10 minutes at room temperature. Finally,
302 neutrophils were resuspended as mentioned in 2.5.1. section.

303

304 *2.5.3. Isolation of neutrophils using Lymphoprep[™]*

305 This method was developed in the present study and it was based on the previous
306 PBMCs isolation protocol explained in 2.2.2. section. Afterwards, exclusively the RBC layer,
307 located underneath the PBMCs and Lymphoprep[™] fraction, was collected and diluted with 20
308 ml of 0.03% sodium bicarbonate for 20 seconds for the lysis of erythrocytes. The isotonicity
309 was restored adding 20ml of PBS/EDTA and neutrophils were pelleted at 300 x g for 10
310 minutes at 4°C. If the presence of erythrocytes observed with the naked eye was suspected, a
311 second lysis step was performed with 5 ml of 0.03% sodium bicarbonate. Finally, neutrophils
312 were washed with PBS/EDTA at 300 x g for 10 minutes and resuspended as mentioned in 2.5.1.
313 section.

314

315 *2.5.4. Morphologic characterization of neutrophils*

316 In order to study the purity of neutrophils in the cell population obtained in each
317 isolation procedure, isolated neutrophils were observed using direct microscopy after Diff-
318 Quick[™] staining following manufacturer's instructions (Auto-Hemacolor[®]). Besides, isolated
319 neutrophils through the three methods already explained, were further characterized through the
320 flow cytometry analysis of 10.000 events (MACSQuant, MiltenyiBiotec[®]) and the purity was
321 expressed as percentage of neutrophils estimated using SCC:FSC plots, gating the expected
322 location of this population using the MACSQuantify10 Software[™].

323

324 *2.6. Statistical analysis*

325 The total number of isolated PBMCs, the yield of monocytes, number of recovered
326 MDMs with different purification techniques and *in vitro* conditions and the data obtained by

327 flow cytometry (percentage of purity, percentage of positive cells and fluorescence intensity)
328 were expressed as mean values of the three animals of each animal species and standard
329 deviations, calculated using conventional descriptive statistical procedures.

330 Multivariate analyses were used according to the nature of the data. Specifically, we
331 used linear models (LM) and generalized linear models (GLMs) with binomial distribution to
332 analyze the effect of the isolation technique (buffy-coat and buffy-coat plus RBC layer) and the
333 animal species (sheep and goats) on the log-transformed number of number of PBMCs isolated
334 and the percentage of purity detected, respectively. At the same time, we used GLMs with
335 binomial and Poisson distributions to explore the effects of cell type (monocyte and MDMs),
336 purification technique (adherence method and immunomagnetic columns), cell phenotype
337 (CD14⁺, MCH-II⁺ and CD11b⁺) and animal species on the percentage of positive cells and
338 fluorescence intensity detected, respectively. The effect of the animal species and the
339 purification techniques (adherence method and immunomagnetic columns) on the yield of
340 monocytes and the number of recovered MDMs with different purification techniques was
341 assessed using GLMs with binomial and Poisson distributions, respectively. The different
342 variables considered in the yield of MDMs with different *in vitro* conditions, such as cell
343 stimulation with GM-CSF and autologous serum and its different concentrations, and animal
344 species were analyzed with GLMs with binomial distribution. Finally, to analyze the variation
345 observed in the purity of neutrophils (expressed as percentage of neutrophils) estimated in each
346 isolation techniques used (without density gradients, Percoll[®] and Lymphoprep[™]) as well as in
347 each animal species, GLMs with binomial distribution were used.

348 The *dredge*, *get.models* and *model.sel* functions included in R package “MuMIn” were
349 used to construct a set of candidate models with all the possible combinations of predictive
350 variables, and according to these, the best model was identified using an automatic selection
351 procedure based on the Akaike Information Criterion corrected for small sample sizes (AICc)
352 (Burnham and Anderson, 2002). The most strong and parsimonious model was selected using
353 the combination of lower AICc and R^2_L (Hosmer-Lemeshow test in binomial regression) and
354 higher R^2 (determination coefficient adjusted by the Kullback-Leibler divergence in Poisson

355 regression). Subsequently, to evaluate the differences between groups within the relevant
356 variables included in the final fitted model, we used the Tukey's Honest Significant Difference
357 adjustment for the pair-wise comparisons using the *glht.function* with "multcomp" package in R
358 (Hothorn et al., 2008). *P* values of less than 0.05 were considered statistically significant. All
359 the statistical analyses were performed with the R Software version 3. 3. 2 (R Development
360 Core Team, 2017).

361

362 **3. Results**

363 *3.1. Efficiency of PBMCs isolation*

364 The final cell count and percentage of purity of isolated PBMCs from both isolation
365 techniques (2.2.1. and 2.2.2.) were expressed as mean values and standard deviations by bar
366 plots (Fig. 2A and 2B). The variables animal species and isolation techniques were included in
367 the best ranked model (Supplementary Table 1). Thus, the number of caprine PBMCs isolated
368 from buffy-coat plus RBC layer was significantly greater (8.50×10^7 PBMCs on average) than
369 the isolated ones only from buffy-coat (3.40×10^6 PBMCs on average) ($\beta = 4.38$, $SE = 1.13$, $p =$
370 0.018). However, in sheep, despite the fact that the number of PBMCs isolated from the buffy-
371 coat plus RBC layer was greater (4.40×10^7 PBMCs and 1.89×10^7 PBMCs respectively) no
372 statistical differences were shown ($\beta = 2.87$, $SE = 1.11$, $p = 0.064$) (Fig. 2A). Furthermore,
373 considering the flow cytometry results (Supplementary Figure 2 and Table 2), when analyzing
374 the isolation technique, the percentage of purity of PBMCs detected from buffy-coat plus RBC
375 layer was also significantly higher compared to buffy-coat alone (90% and 60% on average,
376 respectively) ($OR = 1.95$, 95%, $p = 0.012$). In turn, despite the fact that no differences in the
377 percentage of purity of PBMCs were observed between both isolation techniques in sheep (92%
378 and 91%), a significant higher purity (96%) of caprine PBMCs was observed when buffy-coat
379 plus RBC was employed in contrast to buffy-coat alone (29%) (Fig. 2B). These pairwise
380 comparisons of the best ranked model can be seen in detail (Supplementary Table 3).

382 3.2. Monocyte yield according to purification method

383 The mean values and standard deviations of yield of monocytes were represented (Fig.
384 3). The purification technique reflected significant differences in the monocytes yield. In fact,
385 the immunomagnetic columns technique showed a significant higher yield percentage of
386 monocytes (18%) than the adherence method (4%) (OR = 4.23, 95%, $p < 0.001$). Additionally, a
387 lower monocytes yield was observed in sheep (1.6% by adherence method and 17% by
388 immunomagnetic columns) in comparison to goats (6 % and 18% respectively) without
389 significant statistical differences (OR = 0.75, 95%, $p = 0.42$) (Supplementary Table 4).

390

391 3.3. Efficiency of culture conditions

392 In the best ranked model, the additive effect of the three variables (animal species, cell
393 stimulation and concentrations) were considered (Supplementary Table 5). No significant
394 differences were observed in the yield of recovered MDMs between animal species (OR = 1.44,
395 95%, $p = 0.890$). Furthermore, the number of recovered MDMs was higher in those monocytes
396 supplemented with GM-CSF (5.19×10^5 MDMs on average) in contrast with those supplemented
397 with autologous serum (6.21×10^4 MDMs) (Fig. 4) although no statistical differences were found
398 (OR = 2.71, 95%, $p = 0.839$). Additionally, a gradual increase in the yield was observed as the
399 GM-CSF and autologous serum concentrations were increased (OR = 1.01, 95%, $p = 0.687$).

400

401 3.4. Yield MDMs according to the purification techniques

402 The mean values and standard deviations of the number of recovered MDMs with
403 different purification techniques were represented (Fig. 5). Only the purification technique was
404 included as a variable of interest in the regression models (Supplementary Table 6) and,
405 therefore, the additive effect or interaction with the other variables were not considered. Thus,
406 there was a significant increase in the number of MDMs obtained by the adherence method
407 (5.47×10^5 MDMs on average) in comparison to immunomagnetic columns (3.27×10^5 MDMs on
408 average) in both animal species ($\beta = 0.21$, SE = 0.06, $p = 0.004$).

409

1
2 410 *3.5. Phenotypic characterization of monocytes and MDMs*
3

4 411 When comparing the size of monocytes purified from sheep and goats on the first day,
5
6 412 with the size of MDMs from both animal species after seven days of culture regardless
7
8 413 purification technique used, an increase was observed, mainly due to the expansion of the
9
10 414 cytoplasm. In addition, two different morphologies were noticed both in sheep and goats: an
11
12 415 amoeboid shape or a round aspect. Furthermore, an increase in the granularity could be noticed
13
14 416 inside the cytoplasm of MDMs, which was not observed in the monocytes.
15

16
17 417 An analysis of the morphology and the expression of the surface markers CD14, MHC-II and
18
19 418 CD11b were carried out in monocytes and MDMs obtained by adherence method or
20
21 419 immunomagnetic columns. Monocyte population showed less SCC and FSC signals than
22
23 420 MDMs, in agreement with the increased size and granularity of the latter. Purified monocytes
24
25 421 through adherence method appeared more disperse than those monocytes purified through
26
27 422 immunomagnetic columns, consistent with the presence of greater cell heterogeneity among
28
29 423 those cells purified by adherence method (Fig. 6). However, these differences disappeared when
30
31 424 analyzing the MDMs obtained by either technique (Fig. 6).
32
33

34
35 425 Descriptive statistics of the percentage of positive cells in relation to the different
36
37 426 variables are summarized in Table 1. The animal species and cell phenotype (CD14, MHC-II
38
39 427 and CD11b) were included in the worst-ranked models, which showed their little influence on
40
41 428 the changes observed in the percentage of positive cells (Supplementary Table 7) and the results
42
43 429 were consolidated by the multi-model inference.
44
45

46
47 430 Thus, the interaction of the purification techniques with the cell type showed significant
48
49 431 effects on the percentage of positive cells detected. Specifically, monocytes purified by
50
51 432 immunomagnetic columns showed an increase of the percentage of positive cells (OR = 16.58,
52
53 433 95%, $p = 0.001$) compared to the monocytes purified by the adherence method. However, once
54
55 434 maturation of purified monocytes by the adherence method occurs, there was an increase of the
56
57 435 percentage of positive cells (OR = 0.41, 95%, $p = 0.003$). All pairwise comparisons of the best
58
59 436 ranked model can be seen in the Supplementary Table 8.

437 Descriptive statistics of the fluorescence intensity in relation to the different variables
438 were summarized in Table 2. The best GLM included cell type, cell phenotype and animal
439 species and its interactions as explanatory variables of interests. The purification technique and
440 its relationship with the rest of the variables were included in the worst-ranked models
441 (Supplementary Table 9). Consequently, the fluorescence intensity of MDMs increased
442 significantly in contrast with the monocytes for the three surface markers evaluated, being
443 MHC-II the surface marker with the greatest fluorescence intensity (Table 2). The differences
444 between different interactions can be seen in supplementary Table 10.

445

446 *3.6. Isolation of neutrophils*

447 Although neutrophils were present in the samples obtained by the three methods
448 assessed, qualitative differences were revealed when they were observed directly under
449 microscope. A high number of erythrocytes and PBMCs were detected when neutrophils were
450 isolated without density gradients and similar results were observed with the use of Percoll[®],
451 including a higher number of PBMCs together with dead cells. However, the isolation of
452 neutrophils through centrifugation with Lymphoprep[™] was the method that yielded the higher
453 proportion of neutrophils and the least contamination with PBMCs in both animal species.

454 Qualitative results mentioned above were supported by purity percentages of the
455 isolated neutrophils estimated by flow cytometry (Fig. 7 and 8). The animal species and the
456 isolation technique influenced the percentage of purity. When both variables were included in
457 the best ranked model (Supplementary Table 11), the Lymphoprep[™] technique showed the
458 highest percentage of purity (90% on average) compared to the rest of the techniques used (60%
459 without density gradients and 58% with Percoll[®]) (OR= 1.72, 95%, $p = 0.021$). The isolation
460 without density gradients and the isolation with Percoll[®] did not show significant relevance
461 between them (OR= 0.15, 95%, $p = 0.995$). In addition, the percentage of neutrophils detected
462 in sheep (46-82%) was significantly lower (OR= 0.45, 95%, $p = 0.016$) than in goats (66-95%)
463 in the three methods (Fig. 7). The low purity of the neutrophils isolated from sheep isolation
464 without density gradients or with Percoll[®] was shown by the dispersion of events in the

467

468 **4. Discussion**

469 The purpose of this work was to compare for the first time different protocols for the
470 isolation of neutrophils and monocytes, and the subsequent generation of MDMs from sheep
471 and goats blood with the aim to propose a standardized and agreed method to be used in these
472 ruminant species. The result of these comparisons is a method that allows the simultaneous
473 isolation of highly pure populations of neutrophils and monocytes from the same sample of
474 blood and the posterior maturation of the latter to MDMs.

475 Monocytes and macrophages play an important role as the first line of defense against
476 pathogens as well as a link between innate and adaptive immune responses (Auffray et al.,
477 2009). Therefore, their isolation and manipulation under cell culture conditions is an essential
478 tool for the study of the pathogen-host interaction (Altreuther et al., 2001), with great
479 importance in a high number of small ruminant diseases (e.g. paratuberculosis and
480 toxoplasmosis). According to Peterson et al. (2006), the percentage of peripheral blood
481 monocytes in small ruminants is physiologically low ($17 \pm 24.9\%$ on average). Thus, when a
482 significant number of monocytes is required for *in vitro* studies, the common strategy is to
483 isolate PBMCs and subsequently, purify the monocyte fraction (Marino et al., 2017). The
484 current protocols for PBMCs isolation employed in small ruminants vary widely (Chan et al.,
485 2002; Keane et al., 2002; Peterson et al., 2006; Abendaño et al., 2014); however, among these
486 differences, the centrifugation of diluted blood followed by a centrifugation in a density gradient
487 seems to improve the isolation of PBMCs with a high purity (Keane et al., 2002). Similarly, our
488 results suggest that dilution of blood during the first centrifugation step improves significantly
489 the purity and the number of the PBMCs obtained and, thus, a better further purification of
490 monocytes.

491 Regarding the purification of monocytes, two different procedures (adherence method
492 and immunomagnetic columns) based on previous studies in ruminant species (Olivier et al.,

2001; Budhia et al., 2006; Machugh et al., 2012; Berg et al., 2013) were here compared in sheep and goats. The adherence method is based on the lack of adhesion capacity of the other cells found in the PBMCs fraction, mainly lymphocytes, which allows their elimination during the washing steps (Taubert et al., 2009; Crespo et al., 2013; Elmowalid et al., 2013). As this procedure is based on the seeding of a high number of PBMCs, the initial population of PBMCs after first washing have a low purity of adherent monocytes. The possible presence of significant amounts of contaminating platelets in our samples of monocytes should be considered, as it has been demonstrated to occur when adherence methods of purification are used (Urata et al., 2008), and this may have an impact on the phenotypic characteristics of monocytes (Beliakova-Bethell et al., 2014; Nielsen et al., 2020). To solve this situation, methods based on a double centrifugation with density gradients have been proposed for removing platelets (Casale and Kaliner., 1982), as well as the performance of consecutive washes, as done in this study, that may also be able to significantly reduce the number of platelets (Ceciliani et al., 2007; Ceciliani et al., 2020). The elimination of monocytes that have not been adhered after three hours of incubation and were removed during the washes might also explain the low yield obtained by adherence method. In contrast, purification of monocytes throughout immunomagnetic columns (Abendaño et al., 2013; Pomeroy et al., 2016) has allowed the collection of an initial monocyte suspension with a high percentage of purity and considerably reduce lymphocyte and platelet contamination (Nielsen et al., 2020). However, the isolation of monocytes using antibodies against CD14 receptor, might entail a lower yield since only a certain type of subpopulations of monocytes would be preselected. Nonetheless, some studies have reported that the CD14⁺ surface marker is highly expressed in all monocyte subsets of sheep and goats (Elnaggar et al., 2016) with the CD14⁺CD16⁺⁺ subpopulation being the main monocytes subpopulation in sheep (Corripio-Miyar et al., 2015). In addition, it has to be considered that, despite being an antibody raised for human monocyte recognition, a cross-reaction with ruminants monocytes has been previously demonstrated and the use of immunomagnetic columns labelled with CD14 antibody is considered as a useful and effective

1
2 520 tool for the determination of monocytes subpopulations, cytokines profiles and functional
3 521 studies in ruminants (Budhia et al., 2006; Corripio-Miyar et al., 2015).

4 522 Generation of ruminant MDMs takes place under optimal conditions of *in vitro* culture
5
6 523 and numerous studies suggest the employment of supplemented medium with autologous
7
8 524 serum, cytokines or growth factors in order to facilitate the *in vitro* generation (Keane et al.,
9
10 525 2002; Crespo et al., 2013; Wynn et al., 2013). Here in, we have selected the two main
11
12 526 procedures previously explained: the use of GM-CSF and autologous serum. The GM-CSF
13
14 527 cytokine is expressed mainly in myeloid cell populations, such as monocytes and macrophages
15
16 528 favoring their survival, activation and maturation (Rey-Giraud et al., 2012; Draijer et al., 2019)
17
18 529 and it has been shown to stimulate the *in vitro* proliferation and maturation of macrophages
19
20 530 (Burgess and Metcalf, 1980). Under our experimental conditions, the supplementation with
21
22 531 GM-CSF notably improved the generation of MDMs regard to the supplementation with
23
24 532 autologous serum. The effect of GM-CSF was more evident in ovine than in caprine MDMs,
25
26 533 which may be explained due to the specificity of the ovine GM-CSF used in the stimulation. In
27
28 534 this regard, there is not an agreement on the optimal concentration of GM-CSF in the literature
29
30 535 (Budhia et al., 2006; Souza, 2015). In our study, increased concentrations of GM-CSF resulted
31
32 536 in a higher number of MDMs and we can even assert that GM-CSF was essential for the
33
34 537 generation of MDMs. In contrast, other studies showed that GM-CSF was not essential to obtain
35
36 538 MDMs and the exclusive use of FBS or autologous serum was enough for the generation of
37
38 539 MDMs (Berger and Griffin, 2006; Elmowalid, 2012). Nevertheless, in our study, the use of
39
40 540 different autologous serum concentrations led to the obtaining of a lower number of MDMs
41
42 541 than the use of GM-CSF.

43
44 542 Remarkably, under the same conditions of maturation (supplementation with GM-CSF),
45
46 543 a higher number of MDMs was obtained from purified monocytes with the adherence method
47
48 544 than with immunomagnetic columns despite of the purity of monocytes was greater in this
49
50 545 latter. This result is clearly in contrast with previous studies, carried out with human PBMCs,
51
52 546 where the positive selection of CD14⁺ cells was the preferred method for the generation of
53
54 547 MDMs (Nielsen et al., 2020). One possible explanation for the lack of efficiency of magnetic

548 separation may be related to the low cross-reaction between the human anti-CD14 antibody and
549 the CD14 membrane receptors of ruminants. Nonetheless, this same reagent and the
550 immunomagnetic columns has been employed for the study of MDMs or dendritic cells in sheep
551 and cattle (Budhia et al., 2006; Pomeroy et al., 2016).

552 In order to analyze the influence of the different purification techniques on the
553 subsequent generation of MDMs, a phenotypical characterization of the cells was carried out.
554 As monocytes and MDMs have a remarkable phenotypical and functional heterogeneity, it is
555 convenient to analyze different parameters, such as morphological changes or the expression of
556 surface markers (Gordon and Taylor, 2005; Crespo et al., 2013) for a further characterization of
557 the cells. In addition, a functional characterization needs to be also carried out. The evaluation
558 of morphological changes was most informative when analyzing MDMs as showed an increase
559 in size and changes in shape, ranging from rounded to amoeboid forms along with an increase in
560 granularity in the cytoplasm. In addition, it seems that purification techniques could have an
561 impact on the morphology of monocytes observed in SCC:FSC plots, since a greater yield of
562 monocytes as well as a more homogeneous population was obtained by immunomagnetic
563 columns than with adherence method. However, the manipulation of purified monocytes during
564 the adhesion and subsequent separation from the plate by mechanical methods might also
565 contributed to alter their morphology and therefore, be associated with a more heterogeneous
566 appearance. Interestingly, no differences were observed in MDMs morphology coming from
567 monocytes purified by adherence method or immunomagnetic columns. This analysis proved
568 the usefulness of the morphological characterization of MDMs obtained under *in vitro*
569 conditions (Olivier et al., 2001; Weiss et al., 2002; Jensen et al., 2014). In addition, the analysis
570 of surface markers gave us information about purity of both cell populations (monocytes and
571 MDMs). The analysis of CD14, MHC-II and CD11b showed that purification of monocytes
572 through immunomagnetic columns produced a higher percentage of cells expressing these
573 markers than those isolated by adherence method. Immunomagnetic enrichment has been
574 proven to be an efficient procedure to select CD14⁺ cells, allowing the obtaining, in sheep and
575 cattle, cell populations with a 80-90% of CD14⁺ cells (Budhia et al., 2006; Jensen et al., 2014)

576 from a PBMC fraction that usually contains 4.1% of CD14⁺ cells (Corripio-Miyar et al., 2015).
577 However, it should be also noted that small ruminant granulocytes could also express CD14
578 (Elnaggar et al., 2016), which could reduce the specificity of the immunomagnetic purification
579 of monocytes. Thus, it is important to analyze other surface markers that could help to evaluate
580 the phenotypic characterization of cells and purity (Chan et al., 2002; Elmowalid, 2012). The
581 adherence method led a lower percentage of positive cells expressing CD14, MHC-II and
582 CD11b surface markers. Rather than purifying less number of cells expressing these markers, it
583 is probable that the low percentage of positive cells obtained was a consequence of the higher
584 number of cells that remained adhered to the surface of the plate during the first hours after
585 seeding and that would be lost in the subsequent washing steps. Similarly, activation of
586 monocytes caused with the adherence procedure or the influence of the higher proportion of
587 contaminating lymphocytes, could also alter the expression of surface markers and/or cytokines
588 (Nielsen et al., 2020) which could also explain differences here observed.
589 These findings are in contrast with the results obtained in previous studies where monocytes
590 purified by adherence method gave a purity of 93.5% (Elmowalid, 2012). However, there are
591 significant methodological differences such as the technique used to assess phenotypic
592 characterization (indirect fluorescence assay under fluorescent microscopy), which may explain
593 these discrepancies. Most authors carry out CD14 analysis in order to characterize monocytes
594 purified both by immunomagnetic columns and adherence method (Olivier et al., 2001; Budhia
595 et al., 2006; García-Sánchez et al., 2019) but the preselection of CD14⁺ monocytes could justify
596 the high percentage of positive cells, consequently, this study also analyzes the expression of
597 MHC-II and CD11b to supports that CD14⁺ cells isolated were consistent with monocytes.
598 However, in the study carried out by Nielsen et al. (2020), it was observed a decrease in the
599 expression of CD14 after the use of immunomagnetic columns which was associated with the
600 internalization of the receptors due to the binding with the CD14 conjugated microbeads.
601 Moreover, it is known that as adherence method, the bounding between the CD14 antibody
602 coated into the magnetic beads and the CD14 membrane molecule may change the phenotype of

1
2 603 monocytes, either in their morphology or in the cytokines that they produce, such as IFN- γ ,
3 604 TNF- α or IL-12 (Fikri et al., 2000; Kowalewicz-Kulbat et al., 2016).

4 605 Regarding the analysis of surface markers in MDMs, there was a clear difference in the
5
6 606 measurement of the fluorescence intensity labelling of all surface markers between monocytes
7
8 607 and MDMs, regardless the purification technique. This result is in agreement with Olivier et al.
9
10 608 (2001), who described an increase in the intensity of expression of CD14 and MHC-II in MDMs
11
12 609 after four days of cell culture, in contrast to monocytes. Furthermore, the increase in expression
13
14 610 of MHC-II and CD11b has been described in numerous studies as a reliable indicator of
15
16 611 monocyte maturation (Berger and Griffin, 2006; Elmowalid, 2012).

17
18
19 612 There are several protocols published in the literature for the isolation of neutrophils
20
21 613 with a wide variation on their methodologies (Paltrinieri et al., 2000; Siemsen et al., 2014).
22
23 614 Among three protocols here employed, the isolation of neutrophils without density gradients
24
25 615 was ineffective (50-60% of purity) due to the great contamination with erythrocytes and PBMCs
26
27 616 in both species. Although the gate established for neutrophil identification at flow cytometry, by
28
29 617 size and granularity, suggested a 50-60% of purity among isolated neutrophils from both goats
30
31 618 and sheep, a subsequent visual analysis through Diff Quick™ staining showed a high
32
33 619 contamination. Neutrophils isolated from sheep showed large numbers of erythrocytes and dead
34
35 620 lymphocytes, while in goats, the number of neutrophils was higher but they were highly
36
37 621 contaminated with PBMCs. Therefore, purity obtained by this method was very low, which
38
39 622 disagrees with the purity above 60-70% in sheep using similar protocols (Mulder and Colditz,
40
41 623 1993; Sartorelli et al., 1999; Paltrinieri et al., 2000), which could be explained by differences in
42
43 624 the methodology (lysis buffer and/or evaluation of further purity). Nevertheless, a purity around
44
45 625 60% was obtained when processing bovine blood with similar methods (Ordóñez et al., 2008).
46
47 626 In this sense, previous studies claimed that the main contamination of isolated neutrophils was
48
49 627 due to lymphocytes, as they could make up to 30% of the cells from the RBC fraction, so
50
51 628 centrifugation with Percoll® as a density gradient was advised in order to avoid contamination
52
53 629 by PBMCs (Woldehiwet et al., 2003). The use of Percoll® in the current study improved the
54
55 630 purity of neutrophils in both species despite of a significant contamination by erythrocytes and

631 cellular debris, which was more marked in sheep and might be explained by the different
632 density of ovine and caprine neutrophils (Siemsen et al., 2014). Despite previous results showed
633 a high efficiency, the use of Percoll® at 65% (Woldehiwet et al., 2003; Siemsen et al., 2014) did
634 not allowed us the isolation of a pure population of neutrophils. The reasons for this discrepancy
635 are not clear, although small differences in the methods applied might be involved.

636 The third protocol here employed for neutrophils isolation using Lymphoprep™
637 achieved an effective method for the isolation of small ruminant PBMCs and further
638 purification of monocytes that can also permit the separation of RBCs fraction and PBMCs. The
639 results showed a purity of 80% in sheep and 90% in goats and with a minimal contamination of
640 PBMCs. Silva et al. (2014) proposed a similar protocol for the isolation of caprine neutrophils
641 using Biocoll® instead of Lymphoprep™, although the purity was not estimated. These results
642 are in contrast with those obtained by Woldehiwet et al. (2003), who using Percoll® at 55%
643 (with an identical density to Lymphoprep™ or Biocoll®) achieved a lower purity of neutrophils
644 than using concentrations of Percoll® above 65%.

645

33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 55 56 57 58 59 60 61 62 63 64 65 646 **5. Conclusions**

647 The proposed protocol based on the use of Lymphoprep™ allows the simultaneous
648 isolation of PBMCs and neutrophils in sheep and goats with a high purity. The PBMCs obtained
649 could be further purified for the purification of monocytes, and their subsequent generation of
650 MDMs by both adherence method and immunomagnetic columns. Although the purification
651 with immunomagnetic columns leads a population with a higher purity of monocytes than the
652 adherence method, this latter allows the obtaining of a greater number of MDMs. Thus, a
653 reliable and efficient protocol for the isolation of neutrophils and monocytes has been proposed
654 in this work together with the establishment of the optimal conditions for the subsequent *in vitro*
655 generation of MDMs, with the aim of standardize the procedures to be used when the study of
656 these cell populations is required in small ruminants.

886

887 **Figure captions**

888 **Fig. 1. Scheme of protocols of PBMC isolation techniques from buffy-coat alone (2.2.1. section) and**
889 **buffy-coat plus RBC (2.2.2. section).** Each protocol was carried out using 200 ml of blood. Isolated
890 PBMCs were washed three times before counting and flow cytometry analysis.

891

892 **Fig. 2. Efficiency of PBMCs isolation by two different methods in sheep and goats from the same**
893 **blood sample (200 ml).** (A) Total number of isolated PBMCs. (B) Percentage of purity of isolated
894 PBMCs. Bars represent the mean values whereas the vertical lines represent the standard deviations. *
895 and ** symbols indicate $p < 0.05$ and $p < 0.01$ significant differences, respectively.

896

897 **Fig. 3. Yield of monocytes purified by adherence method (AM) and immunomagnetic columns (IC)**
898 **in sheep and goats.** Data are expressed as mean values and vertical lines represent standard deviations.
899 *** Symbol represents a significant difference of $p < 0.001$.

900

901 **Fig. 4. Yield of MDMs in sheep and goats obtained from purified monocytes by adherence method**
902 **with different cell culture stimulations and concentrations.** Bars represent mean values of total
903 number of MDMs and vertical lines the standard deviations. No significant differences were shown
904 between GM-CSF and autologous serum (AUS) neither between sheep and goats.

905

906 **Fig. 5. Yield of MDMs obtained from monocytes purified by adherence method (AM) and**
907 **immunomagnetic columns (IC) in sheep and goats and supplemented with GM-CSF (60 ng/μl).** Bars
908 and vertical lines represent mean values and standard deviations respectively of the total number of
909 recovered MDMs. Significant difference is expressed as ** symbol ($p < 0.01$).

910

1
2 911 **Fig. 6. Analysis of size (SCC) and complexity (FSC) of monocytes and MDMs in sheep and goats**
3
4 912 **carried out by flow cytometry.** Purified monocytes from sheep and goats by both immunomagnetic
5
6 913 columns (IC) and adherence method (AM), together with ovine and caprine MDMs from purified
7
8 914 monocytes by IC and AM, respectively and supplemented with GM-CSF (60 ng/ml) are represented in
9
10 915 dot plots. A greater heterogeneity is observed in monocytes purified by means of the AM in both species
11
12 916 in contrast with the well-defined population achieved through IC delimited by the red gate. Percentage of
13
14 917 events (SSC:FSC) and mean percentage of CD14⁺, MHC-II⁺ and CD11b⁺ are summarized in each plot.
15
16 918 No differences between purification techniques of monocytes neither animal species were observed in
17
18 919 MDMs populations.

20 920

22 921 **Fig. 7. Efficiency of neutrophils isolation technique (IT) expressed as percentage of purity estimated**
23
24 922 **by flow cytometry.** Bars represent mean values of percentage of neutrophils isolated without density
25
26 923 gradients (WDG), using Percoll[®] and using Lymphoprep[™]. Vertical lines represent standard deviations. *
27
28 924 Symbol indicates a significant difference of $p < 0.05$.

30 925

32 926 **Fig. 8. Analysis of size (SCC) and complexity (FSC) of isolated neutrophils by three different**
33
34 927 **protocols carried out in sheep and goats by flow cytometry.** Neutrophils were isolated without density
35
36 928 gradients (WDG), using Percoll[®] and using Lymphoprep[™]. Neutrophils are represented inside the red
37
38 929 gate. Notice the high degree of heterogeneity of cells isolated WDG and using Percoll[®], which it was
39
40 930 more marked in sheep than in goats and did not correspond to the neutrophils gate. Lymphoprep[™]
41
42 931 achieved a well-defined and abundant population of cells corresponding to neutrophils observed inside
43
44 932 the gate in both species.
