Biased Bilayer Graphene: Semiconductor with a Gap Tunable by the Electric Field Effect

The electronic structure of materials is given by their chemical composition and specific arrangements of atoms in a crystal lattice and, accordingly, can be changed only slightly by external factors such as temperature or high pressure. In this Letter we show, both experimentally and theoretically, that the band structure of bilayer graphene can be controlled by an applied electric field so that the electronic gap between the valence and conduction bands can be tuned between zero and midinfrared energies. This makes bilayer graphene the only known semiconductor with a tunable energy gap and may open the way for developing photodetectors and lasers tunable by the electric field effect. The development of a graphene-based tunable semiconductor being reported here, as well as the discovery of anomalous integer quantum Hall effects (QHE) in single-layer [1, 2] and unbiased bilayer [3] graphene, which are associated with massless [4] and massive [5] Dirac fermions, respectively, demonstrate the potential of these systems for carbon-based electronics [6]. Furthermore, the deep connection between the electronic properties of graphene and certain theories in particle physics makes graphene a test bed for many ideas in basic science.

Below we report the experimental realization of a tunable-gap graphene bilayer and provide its theoretical description in terms of a tight-binding model corrected by charging effects (Hartree approach) [7]. Our main findings are as follows: (i) in a magnetic field, a pronounced plateau at zero Hall conductivity $\sigma_{xy} = 0$ is found for the biased bilayer, which is absent in the unbiased case and can only be understood as due to the opening of a sizable gap, $\Delta_g$, between the valence and conductance bands; (ii) the cyclotron mass, $m_c$, in the bilayer biased by chemical doping is an asymmetric function of carrier density, $n$, which provides a clear signature of a gap and allows its estimate; (iii) by comparing the observed behavior with our tight-binding results, we show that the gap can be tuned to values larger than 0.2 eV; (iv) we have cross-checked our theory against angle-resolved photoemission spectroscopy (ARPES) data [8] and found excellent agreement. The devices used in our experiments were made from bilayer graphene prepared by micromechanical cleavage of graphite on top of an oxidized silicon wafer (300 nm of SiO$_2$) [9]. By using electron-beam lithography, the graphene samples were then processed into Hall bar devices similar to those reported in Refs. [1–3]. To induce charge carriers, we applied a gate voltage $V_g$ between the sample and the Si wafer, which resulted in carrier concentrations $n_1 = \alpha V_g$ due to the electric field effect. The coefficient $\alpha \approx 7.2 \times 10^{10} \text{cm}^{-2}/\text{V}$ is determined by the geometry of the resulting capacitor and is in agreement with the values of $n_1$ found experimentally [1–3]. In order to control independently the gap value and the Fermi level $E_F$, the devices could also be doped chemically by exposing them to NH$_3$ that adsorbed on graphene and effectively acted as a top gate providing a fixed electron density $n_0$ [10]. The total bilayer density $n$ is then $n = n_1 + n_0$ relatively to half filling. The electrical measurements were carried out by the standard lock-in technique in magnetic fields up to 12 T and at temperatures between 4 and 300 K.

We start by showing experimental evidence for the gap opening in bilayer graphene. Figure 1(a) shows the measured Hall conductivity of bilayer graphene, which allows a comparison of the QHE behavior in the biased and unbiased cases. Here the curve labeled “pristine” shows the anomalous QHE that is characteristic of the unbiased bilayer [3]. In this case, the Hall conductivity exhibits a sequence of plateaus at $\sigma_{xy} = 4Ne^2/h$ where $N$ is integer and the factor 4 takes into account graphene’s quadruple degeneracy. The $N = 0$ plateau is strikingly absent, so that a double step of $8e^2/h$ in height occurs at $n = 0$, indicating a metallic state at the neutrality point [3]. Note that the backgate voltage induces asymmetry between the two layers but QHE measurements can only probe states close to the Fermi level. Figure 1(b) shows the opening of a gap is clearly seen in the quantum Hall regime.
To gain further information about the observed gap, we measured the cyclotron mass of charge carriers and its dependence on \( n \). To this end, we followed the same time-consuming procedure as described in detail in Ref. [1] for the case of single-layer graphene. In brief, for many different gate voltages, we measured the temperature \( (T) \) dependence of Shubnikov–de Haas oscillations and then fitted their amplitude by the standard expression \( T/\sinh(2\pi^2 k_B T m_c/\hbar eB) \). To access electronic properties of both electrons and holes in the same chemically biased device, we chose to dope it to \( n_0 = 1.8 \times 10^{12} \text{ cm}^{-2} \), i.e., less than in the case of Fig. 1(a). The results are shown in Fig. 1(b). The linear increase of \( m_c \) with \( |n| \) and the pronounced asymmetry between hole- and electron-doping of the biased bilayer are clearly seen here.

To explain the observed Hall conductivity and cyclotron mass data for bilayer graphene, in what follows, we shall use a tight-binding description of electrons in bilayer graphene. Its carbon atoms are arranged in two honeycomb lattices labeled 1 and 2 and stacked according to the Bernal order \((A1-B2)\), where \( A \) and \( B \) refer to each sublattice within each honeycomb layer, as shown in Fig. 2(a). The system is parametrized by a tight-binding model where \( \pi \) electrons are allowed to hop between nearest-neighbor sites, with in-plane hopping \( t \) and interplane hopping \( t_\perp \).

Throughout the Letter we use \( t = 3.1 \text{ eV} \) and \( t_\perp = 0.22 \text{ eV} \). The value of \( t \) is inferred from the Fermi-Dirac velocity in graphene, \( v_F = (\sqrt{2}/3)\hbar a/\hbar = 10^6 \text{ ms}^{-1} \), where \( a = 2.46 \text{ Å} \) is the same-sublattice carbon-carbon distance, and \( t_\perp \) is extracted by fitting \( m_c \) (see below).

For the biased system the two layers gain different electrostatic potentials, and the corresponding energy difference is given by \( eV \). The presence of a perpendicular magnetic field \( B = B_z \) is accounted for through the standard Peierls substitution, \( t \rightarrow t \exp[ie \int \mathbf{R} \cdot \mathbf{\hat{A}} \cdot d\mathbf{r}] \), where \( e \) is the electron charge, \( \mathbf{\hat{A}} \) the vector connecting nearest-neighbor sites, and \( A \) the vector potential (in units such that \( e = 1 = \hbar \)).

Figure 2(b) shows the electronic structure of the biased bilayer near the Dirac points \((K \text{ or } K')\). In agreement with the Hall conductivity results in Fig. 1(a), one can see that the unbiased gapless semiconductor (dashed line) becomes, with the application of an electrostatic potential \( V \), a small-gap semiconductor (solid line) whose gap is given by: \( \Delta_g = [e^2 V^2 f_1^2/(f_1^2 + e^2 V^2)]^{1/2} \). As \( V \) can be externally controlled, this model predicts that biased bilayer graphene should be a tunable-gap semiconductor, in agreement with results obtained previously using a contin-
uum model [7]. Note that the gap does not reach a minimum at the $K$ point due to the “Mexican-hat” dispersion at low energies [11].

The electric field induced between the two layers can be considered as a result of the effect of charged surfaces placed above and below bilayer graphene. Below is an accumulation or depletion layer in the Si wafer, which has charge density $n_1 e$. Dopants above the bilayer effectively provide the second charged surface with density $n_0 e$. Assuming equal charge $-n e / 2$ in layers 1 and 2 of the bilayer we find an unscreened potential difference given by

$$V = (2 - n / n_0) n_0 e d / (2 e_0), \quad \text{(1)}$$

where $e_0$ is the permittivity of free space, and $d \equiv 0.34 \text{ nm}$ is the interlayer distance. A more realistic description should account for the charge redistribution due to the presence of the external electric field. For given $V$ and $n$, we can estimate the induced charge imbalance between layers $\Delta n(n, V)$ through the weight of the wave functions in each layer (Hartree approach; also, see [7]). This charge imbalance is responsible for an internal electric field that screens the external one, and a self-consistent procedure to determine the screened electrostatic difference requires

$$V = [2 - n / n_0 + \Delta n(n, V) / n_0] n_0 e d / (2 e_0). \quad \text{(2)}$$

Zero potential difference and zero gap are expected at $n = 2 n_0$ in both unscreened and screened cases, as seen from Eqs. (1) and (2) and the fact that $\Delta n(n, 0) = 0$.

In Fig. 2(c) our calculations using Eqs. (1) and (2) are compared with ARPES measurements of the V dependence on $n$ in bilayer graphene by Ohta et al. [8]. In their experiment, $n$-type doping with $n_1^{ex} = 10 \times 10^{12} \text{ cm}^{-2}$ was due to the SiC substrate and therefore fixed. The electronic density $n_0$ induced by the deposition of K atoms onto the vacuum side was then used to vary the total density. A zero gap was found around $n \approx 2.3 \times 10^{12} \text{ cm}^{-2}$ from which value we expect $n_0^{th} = 11 \times 10^{12} \text{ cm}^{-2}$, in agreement with the experiment. In order to compare the behavior of $V$ with varying $n$ we replace $n_0$ in Eqs. (1) and (2) with $n_0 = n - n_1^{th}$. The result for the unscreened case [Eq. (1)]—shown in Fig. 2(c) as a dashed line—cannot describe the experimental data. The solid and dotted lines are the screened results obtained with the self-consistent procedure [Eq. (2)] for $t_{1L} = 0.2 \text{ eV}$ and $t_{2L} = 0.4 \text{ eV}$, respectively; both are in good agreement with the experiment, except in the gap saturation regime at $n \approx 5 \times 10^{12} \text{ cm}^{-2}$

For the experiments described in the present work, the expected behavior of the gap with varying $n$ or, equivalently, $V_g$ is shown in Fig. 2(d). The dashed line is the unscreened result $[V$ given by Eq. (1)] and the solid line is the screened one [Eq. (2)]. In both cases, the chemical doping was set to $n_0 = 1.8 \times 10^{12} \text{ cm}^{-2}$ at which $m_c$ was measured in our experiment (equivalent of $V_g = 25 \text{ V}$). The dashed-dotted (blue) line is a linear fit to the screened result for small gap, yielding $\Delta_g (\text{meV}) = \beta V_g (V - 25)$ with a coefficient $\beta = 1.2 \text{ meV/V}$. The linear fit is valid in the small-gap regime ($\Delta_g \ll t_{1L}$) only, and the theory predicts a gap saturation to $\Delta_g \sim t_{2L}$ at large biases. Note that the breakdown field for SiO$_2$ is $1 \text{ V/mm}$ (i.e., $300 \text{ V}$ for the used oxide thickness) and, therefore, practically the whole range of allowed gaps (up to $t_{1L}$) should be achievable for the demonstrated devices.

To explain the observed behavior of the cyclotron mass, $m_c$, shown in Fig. 1(b), we used the semiclassical expression $m_c(n) = (\hbar^2 / 2\pi) \partial A(E) / \partial [E - E_i(n)]$, where $A(E)$ is the $k$-space area enclosed by the orbit of energy $E$ and $n$ the carrier density at $E_k$. In Fig. 1(b) our theory results are shown as dashed and solid lines for the unscreened and screened description of the gap, respectively, (analytical expressions for $m_c$ in the biased bilayer will be given elsewhere [12]). The interlayer coupling $t_{1L}$ is the only adjustable parameter, as $t$ is fixed and $V$ is given by Eq. (1) or Eq. (2). The value of $t_{1L}$ could then be chosen so that theory and experiment gave the same $m_c$ for $n = 3.6 \times 10^{12} \text{ cm}^{-2}$. At this particular density the gap closes and the theoretical value becomes independent of the screening assumptions. We found $t_{1L} = 0.22 \text{ eV}$, in good agreement with values found in the literature. The theoretical dependence $m_c(n)$ agrees well with the experimental data for the case of electron doping. Also, as seen in Fig. 1(b), the screened result provides a somewhat better fit than the unscreened model, especially at low electron densities. This fact, along with the good agreement found for the potential difference data of Ref. [8] [see Fig. 2(c)], allows us to conclude that for doping of the same sign from both sides of bilayer graphene, the gap is well described by the screened approach. In the hole-doping region in Fig. 1(b), the Hartree approach underestimates the value of $m_c$, whereas the simple unscreened result overestimates it. This can be attributed to the fact that the Hartree theory used here is reliable only if the gap is small compared to $t_{1L}$.

FIG. 3 (color online). Energy spectrum for a ribbon of bilayer graphene with zigzag edges, $t_{1L} / t = 0.2$, $B = 30 \text{ T}$, and width $N = 400$ unit cells: (a) $eV = 0$; (b) $eV = t_{1L} / 10$. (c) Sketch of the bands close to zero energy (for the biased bilayer) with indication of bulk (solid lines) or edge (dotted lines) states and their left ($L$) or right ($R$) positions along the ribbon. Quasiparticle energies have been removed for clarity.
In our experimental case, \( n_0 > 0 \) and, therefore, the theory works well for a wide range of electron doping \( n > 0 \), whereas even a modest overall hole doping \( n < 0 \) corresponds to a significant electrostatic difference between the two graphene layers. In this case, the unscreened theory overestimates the gap whereas the Hartree calculation underestimates it. However, it is clear that the experimental data in Fig. 1(b) interpolate between the screened result at low hole doping and the unscreened one for high hole densities. This indicates that the true gap actually lies between the unscreened and screened limits [see Fig. 2(d)], and that a more accurate treatment of screening is needed when \( eV \) becomes of the order of \( t_L \).

In what follows, we model and discuss the QHE data presented in Fig. 1(a). We consider a ribbon of bilayer graphene [13] with zigzag edges (armchair edges give similar results). Figure 3 shows the energy spectrum in the presence of a strong magnetic field. Figure 3(a) corresponds to the unbiased case [see the curve labeled “pristine,” Fig. 1(a)], where the four degenerate bands at zero energy contain four degenerate bulk Landau levels [5] and four surface states characteristic of the bilayer with zigzag edges [12]. The spectrum for a biased device is shown in Figure 3(b). In this case two flat bands with energies \(-eV/2\) and \(eV/2\) appear, similar to the case of zero magnetic field. The other two zero energy bands become dispersive inside the gap, showing the band-crossing phenomenon. The Landau level spacing is set by \( \gamma = \sqrt{3/2\pi a/\rho} \) (\( \rho \) is the magnetic length), and as long as \( eV \ll t_L \), the bias is much smaller than the Landau level spacing at low fields. Then nonzero Landau levels in the bulk are almost insensitive to \( V \), as seen in Fig. 3(b), except for a small asymmetry between Dirac points. A close inspection of Fig. 3 shows that the valley degeneracy is lifted due to the different nature of the Landau states at \( K \) and \( K' \) valleys with respect to their projection in each layer. The valley asymmetry has a stronger effect in the zero energy Landau levels, where the charge imbalance is saturated. This opens a gap of \( eV \) in size. Also, there is an intravalley degeneracy lifting [Fig. 3(c)], because only one of the two Landau states of the unbiased system remains an eigenstate when a bias is applied. For \( eV \approx t_L \) (not shown in Fig. 3) the dispersive modes start crossing with nonzero bulk Landau levels.

Let us now model the measured Hall conductivity for the biased bilayer graphene, which is shown in the (red) curve labeled doped in Fig. 1(a). We consider the case of the chemical potential lying inside the gap, between the last hole- and the first electronlike bulk Landau levels, and crossing the dispersive bands as shown in Fig. 3(c). As pointed out by Laughlin [14], changing the magnetic flux through the ribbon loop by a flux quantum causes the states to move rigidly towards one edge. In the usual integer QHE, the energy increase due to this adiabatic flux variation results in the net transfer of \( n \times g \) electrons (spin and valley degeneracy \( g \)) from one edge to the other, and the quantization of the Hall conductivity follows the expression [15]:

\[
I/V = gne^2/h
\]

where \( I \) is the current carried around the loop and \( V \) the potential drop between the two edges. However, in the present case there is no net charge transfer across the ribbon. As seen in Fig. 3(c), the band states at the chemical potential belonging to the same band are surface states localized at the same edge (see the figure caption for details). The rigid movement of the states towards one edge makes an electron-hole pair to appear at both edges, resulting in zero net charge transfer. Therefore, we expect a Hall plateau \( \sigma_{xy} = 0 \) showing up when the carriers change sign, i.e., at the neutrality point. Accordingly, the Hall conductivity of the biased bilayer is given by \( \sigma_{xy} = 4N e^2/h \) for all integer \( N \), including zero. Note that at the zero Hall plateau the current carried around the ribbon loop is zero, \( I = 0 \), which implies, from the theory view point, a diverging longitudinal resistivity at low \( T \), in stark contrast to all the other Hall plateaus that exhibit zero \( \rho_{xx} \), as in the standard QHE. This behavior has been observed experimentally, as discussed above with reference to Fig. 1(a). This concludes our interpretation of the experimental data.
