We propose a generalized formulation of stellar speckle interferometry (SSI) and related techniques in terms of joint spatial/spatial-frequency energy representations. We show how, within this formulation, techniques such as that of Knox–Thompson, or even standard SSI, appear to be particular implementations of a more general method. This generalized SSI is derived in a straightforward manner from the proposed joint formulation. Results from a computer simulation are presented.

Stellar speckle interferometry (SSI) is a common technique used in astronomy to attain the diffraction-limit resolution of large ground-based telescopes.\(^1\) Let \(i_t(x)\) be the image of the object \(o(x)\) at time \(t\); then

\[
i_t(x) = o(x) \ast h_t(x),
\]

where \(\ast\) denotes convolution and \(h_t(x)\) is the instantaneous point-spread function of the image-forming system: atmosphere–telescope. Conventional astronomical imaging consists of integrating Eq. (1) during a given exposure time. The resulting image is proportional to the average \(\langle i_t(x) \rangle = o(x) \ast \langle h_t(x) \rangle\). Instead, SSI consists of averaging the power spectra of a set of short-exposure images,

\[
\langle |I_t(u)|^2 \rangle = |O(u)|^2 \langle |H_t(u)|^2 \rangle.
\]

By applying the same averaging procedure to a reference point star it is possible to estimate \(\langle |H_t(u)|^2 \rangle\). Thus one could solve Eq. (2) to obtain \(|O(u)|^2\) as far as the cutoff frequency of the telescope. Using this technique, one attains the diffraction limit at the cost of missing the phase of \(O(u)\). Consequently one cannot reconstruct the object \(o(x)\), since the Fourier transform (FT) of \(|O(u)|^2\) gives the autocorrelation \(Q(\Delta x)\) of the object, instead of \(o(x)\). Several methods have been proposed to keep the information about the phase in SSI\(^3\) (see Ref. 9 for a useful review).

In this Letter we propose a formulation of SSI, and related techniques, based on joint energy spatial/spatial-frequency representations. From this powerful analytical framework\(^9,10\) some of the ideas involved in SSI can be generalized. Furthermore, one can find new and possibly more advantageous practical implementations. There are four basic functions in the joint representation: the product function (PF), the Wigner distribution (WD), the ambiguity function (AF), and the spectral product (SP). It is easy to show that the four functions retain both high resolution and phase information. After that, we show how most of the speckle techniques appear in this formulation as particular implementations of a generalized SSI method. Finally, results of a computer simulation are presented.

Following Cohen,\(^10\) a general expression for a class of joint energy representations is given by

\[
E(x, u; \phi) = \frac{1}{(2\pi)^N} \int \int^{\pm \infty} \phi(\xi, \alpha) \delta(\rho - \alpha/2) e^{i\rho x} d\alpha d\xi d\rho,
\]

where \(x, u, \xi, \alpha,\) and \(\rho\) are vectors in the general \(N\)-dimensional case. The function \(\phi(\xi, \alpha)\) is a kernel that defines a particular representation. When \(\phi(\xi, \alpha) = 1\), then \(E_t\) is the WD.\(^11,12\) The AF is also obtained by placing \(\phi(\xi, \alpha) = 2\pi \delta(\alpha - x) \delta(\xi - u)\) in Eq. (3). It follows that the WD, along with its two single FT’s (PF and SP) and with its double FT (AF), completes the simplest joint energy scheme. Figure 1 indicates the definitions and relations between the four basic functions of this scheme. Any function is computable from another by a single (adjacent in the diagram) or a

$^a A = 2\pi(\alpha - x)$, $B = \exp(2\pi jx/2\Delta u)$.

double (opposite) FT. On the other hand, the WD presents a set of interesting properties (see Refs. 11 and 12). Among these properties, the convolution theorem allows one to rewrite Eq. (1) in four different ways:

$$P_i(x, \Delta x) = [P_\gamma(\xi, \eta) \otimes P_\Delta(\xi, \eta)]_{(x, \Delta x)};$$  \hspace{1cm} (4a)

$$W_i(x, u) = [W_\gamma(\xi, \eta) \otimes W_\Delta(\xi, \eta)]_{(x, u)};$$  \hspace{1cm} (4b)

$$A_i(\Delta x, \Delta u) = [A_\gamma(\eta, \Delta u) \otimes A_\Delta(\eta, \Delta u)]_{(\Delta x)};$$  \hspace{1cm} (4c)

$$K_i(u, \Delta u) = K_\gamma(u, \Delta u)K_\Delta(u, \Delta u).$$  \hspace{1cm} (4d)

Equations (4) indicate that the convolution in Eq. (1) becomes a double convolution (in $x$ and $\Delta x$) in the domain of the PF; it is a single convolution in both joint domains and a product in the domain of the SP.

In practice, there are two alternatives to implement SSI, one by averaging the power spectrum of short-exposure images and the other by averaging the autocorrelations.$^2$ Both the power spectrum and autocorrelation are energy representations of the signal. In the joint scheme we can compute four equivalent averages:

$$\langle P_i(x, \Delta x) \rangle = \langle i^*(x - \Delta x/2)i(x + \Delta x/2) \rangle;$$  \hspace{1cm} (5a)

$$\langle W_i(x, u) \rangle = \int_{-\infty}^{+\infty} d\Delta x \langle P_i(x, \Delta x) \rangle \exp(-2\pi ju\Delta x),$$  \hspace{1cm} (5b)

$$\langle A_i(\Delta x, \Delta u) \rangle = \int_{-\infty}^{+\infty} dx \langle P_i(x, \Delta x) \rangle \exp(-2\pi jx\Delta u),$$  \hspace{1cm} (5c)

$$\langle K_i(u, \Delta u) \rangle = \int \int_{-\infty}^{+\infty} d\Delta x dx \langle P_i(x, \Delta x) \rangle \times \exp[-2\pi j(x\Delta u + u\Delta x)] \times \langle I_t^{*}(u - \Delta u/2)I_t(u + \Delta u/2) \rangle. $$  \hspace{1cm} (5d)

These equations state that it does not matter which of the four functions one averages, since the FT of an average is the average of the FT. It is easy to show that the four averages of $P_i$, $W_i$, $A_i$, and $K_i$ retain both high resolution and phase information. That was dem-

Fig. 2. Resulting averages of the four functions of the joint scheme for both the point (a, c, e, g) and the binary stars (b, d, f, h): a, b, the PF; c, d, the WD; e, f, the AF; g, h, the SP.
and linear phase factors. However, since the triple cases, the kernel is composed of only delta functions to each speckle technique. Note that in almost all particular representations, after Eq. (3), corresponding also shows the adequate kernel $Q$, a) to define the methods to save dimensions, although it is always possible to develop additional intermediate cases, which could perhaps avoid the computation of the FT of every single frame. There are also two advantages: the WD and the AF. Nevertheless, the disadvantages inherent to joint energy representations are that these functions are of $2N$ dimensions, although it is always possible to develop methods to save memory.

The joint formulation permits the unification of most speckle imaging techniques. Table 1 shows the different methods (except triple correlation) can be applied to the averaged PF, $(P(x, \Delta x))$. Table 1 also shows the adequate kernel $\phi(\xi, \alpha)$ to define the particular representation, after Eq. (3), corresponding to each speckle technique. Note that in almost all cases, the kernel is composed of only delta functions and linear phase factors. However, since the triple correlation belongs to a third-order representation class, it is necessary to include $F^*(\Delta u)$ in the kernel. This renders impossible the application of the triple-correlation technique to the PF.

Figures 2 and 3 show the results of a computer simulation. One hundred fifty speckle images of both a binary star and reference were generated by a standard method. Imaging through a 1-m telescope, a Fried parameter of 10 cm, and a wavelength of 0.5 $\mu$m were assumed. The resulting 256 \times 256 frames were integrated in one axis to obtain one-dimensional data. The sampling interval was 5 pixels per speckle grain to avoid possible aliasing problems when computing $\Delta x/2$ and $\Delta u/2$ increments. No noise was added to the frames. Figure 2 shows the results of averaging the four functions $P_i$, $W_i$, $A_i$, and $K_i$ for both the binary and the point stars. The horizontal direction corresponds to $\Delta x$ or $\mu$, while the vertical direction refers to $x$ or $\Delta u$, depending on the case. Figure 3 shows two reconstructions. The solid curve was obtained by first computing $(P(x, \Delta x))$ and then its double FT, while the symbols correspond to direct computing of $(K_i(u, \Delta u))$. In both cases the phase of the FT of the object was obtained by applying the phase-integration method of Knox–Thompson. A Wiener filtering was applied in the deconvolution. The two reconstructions are almost identical, and only the noise levels show small discrepancies.

One may conclude that the formulation presented here permits a generalization of methods such as standard SSI and Knox–Thompson speckle imaging. Furthermore, many other imaging methods, such as the phase gradient, are directly, and alternatively, applicable to the resulting data.
