Key points

- Geochemical and sedimentological signals depict a clear SW-NE gradient that reverses in the Gulf of Lions.
- This gradient is mainly attributed to differences in local primary productivity and delivery of terrestrial organic carbon.
- Organic matter protection by mineral surfaces and lateral transport are proposed as potential additional controls.

Abstract

Marine sediments comprise the primary long-term sink of organic matter (OM) in marine systems. Disentangling the diverse origins of OM and the influence of the main processes that determine organic carbon (OC) fate at a global scale has proven difficult due to limited spatial data coverage. Thus, comprehensive studies of the spatial distribution of the content and geochemical characteristics of sedimentary OM at basin scales provide fundamental knowledge on the role of marine sediments in the global carbon cycle. Here, we shed light on the origin of OM and the underlying mechanisms that determine its fate in a semi-enclosed basin by examining the spatial patterns in the isotopic and elemental composition of OM in 149 core-top samples from the Western Mediterranean Sea and the adjacent Atlantic Ocean sector. Our results reveal an apparent SW-NE gradient that reverses in the Gulf of Lions in most geochemical and sedimentological features. Changes in the OC content and $\delta^{13}\text{C}$ and $\Delta^{14}\text{C}$ signatures are ascribed to spatial variations in marine primary productivity and the influence of varying discharge of rivers and well-developed canyons that favour the cross-shelf transport of terrestrial (and petrogenic) OC. Our results also suggest the potential influence of two other mechanisms on the geochemical signatures of OM: i) lateral transport of allochthonous OC and selective degradation of labile OM, which potentially occurs across the studied area having a greater impact towards the north-eastern region, and ii) OM protection via association with mineral surfaces, potentially having a greater influence towards the south-western basins.

Keywords: organic carbon, radiocarbon, stable isotopes, organo-mineral association, carbon cycle

1. Introduction

Marine sediments are one of the largest global carbon sinks, with continental margins acting as key areas of organic carbon (OC) storage (Atwood et al., 2020; Hedges & Keil, 1995). Understanding the factors and processes that determine the stabilization of organic matter (OM) on continental margins and their adjacent deep oceanic domain is vital to constrain global carbon inventories and carbon cycling. Sedimentary OM is composed of varying proportions of marine and terrestrial OC. Each of these pools may, in turn, combine with freshly produced OC from primary productivity, aged and altered OC that has been retained in the system prior to final burial, and fossil or rock-derived (petrogenic) OC mainly introduced by fluvial transport. Isotopic ($\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and $\Delta^{14}\text{C}$) and elemental (carbon and nitrogen content and atomic C/N ratios) characteristics of sedimentary OM allows to infer contrasting combinations of these three components on the basis of their primary origin and reactivity (Meyers, 1994).

Once in the water column, OM is transformed and degraded by chemical, physical and biological processes (Burdige, 2007), with exposure to oxic conditions playing a major role in favouring OM remineralization. Protection from oxic degradation is promoted via organo-mineral associations (Hemingway et al., 2019; Mayer, 1994a, 1994b). OM sorption onto particle surfaces is greater in finer grains because the latter provide higher surface area to volume ratio. Accordingly, there is a broadly linear relationship between OC content and mineral surface area (SA), which is in turn inversely related to grain size. However, fine-grained minerals may further expose hosted OM to transport under oxic conditions because non-cohesive fine-grained sediments (i.e., silt; 2-63 μm) are more prone to resuspension and subsequent lateral advection than cohesive fine grains (i.e., clay; <2 μm) and coarser grains (i.e., sand; >63 μm) (Ausín et al., 2021). Hence, the

hydrodynamic sorting of fine-grained sediment favours OC degradation (Blair & Aller, 2012). Since hydrodynamic processes play a crucial role in the dispersal and characteristics of sedimentary OM (Ausín et al., 2021; Bao et al., 2018; Bröder et al., 2018; Bruni et al., 2022), the distribution and geochemical composition of OM must be also assessed in a sedimentological context.

Integrated studies on the origin and fate of sedimentary OC at basin scales are limited because it is difficult to disentangle the various biological, physico-chemical, and geological processes that influence the geochemical and sedimentological characteristics of OM. Yet, a comprehensive assessment of the influence of these processes at basin scales is vital in understanding the role of marine sediments in the global carbon cycle.

In this regard, spatially restricted seas provide a natural laboratory to assess in detail the diverse OM origins and varied depositional processes that influence the spatial distribution of the content and geochemical characteristics of sedimentary OM.

Here, we examine the spatial distribution of the content and geochemical characteristics of sedimentary OM in surface sediment samples from the Atlantic sector west of the Strait of Gibraltar and across the Western Mediterranean Sea to improve our understanding of carbon cycling on continental margins and adjacent deep basins and shed light on the underlying processes that might impact OM signals in the sedimentary record and their interpretation in paleoenvironmental studies.

2. Study area

The Western Mediterranean Sea (Fig. 1) is a semi-enclosed basin whose restricted connection to the open ocean allows examination of the major processes that control the distribution and geochemical characteristics of sedimentary OM on continental margins and in neighbouring deeper environments. In this work, the Western Mediterranean has been divided into smaller basins following Bricaud et al. (2002): Alboran Sea, Algerian Basin, Balearic Sea, Algero-Provencal Basin, and Gulf of Lions. Because the Atlantic water enters the Mediterranean Sea through the Strait of Gibraltar and mixes with the more saline, warmer, and oligotrophic Mediterranean water influencing the resulting geochemical signature of Mediterranean surface waters, the adjacent Atlantic sector (SW Iberian margin) west of the Strait of Gibraltar is also included in this study.

The SW Iberian margin is part of the Canary Current Upwelling System and is characterised by strong mesoscale gradients and seasonal variability in upwelling occurrence and primary productivity (Relvas et al., 2007). The Western Mediterranean Sea is considered mesotrophic with annual mean values of net primary production of $131 \pm 6 \text{ g C m}^{-2} \text{ yr}^{-1}$ (Lazzari et al., 2012) due to wind-induced winter mixing and coastal upwelling (Siokou-Frangou et al., 2010). Annual primary production is relatively high in the Alboran Sea ($215\text{-}244 \text{ gC m}^{-2} \text{ yr}^{-1}$ (Bosc et al., 2004)) due to the presence of upwelling cells related to semi-permanent geostrophic fronts associated with the inflow of Atlantic waters (Sarhan et al., 2000). Annual primary production decreases towards the northeast throughout the Algerian Basin, the Balearic Sea, and the Algero-Provencal Basin ($158\text{-}156$, $153\text{-}175$, and $145\text{-}165 \text{ gC m}^{-2} \text{ yr}^{-1}$, respectively (Bosc et al., 2004)). Values are higher in the Gulf of Lions ($180\text{-}204 \text{ gC m}^{-2} \text{ yr}^{-1}$) due to intense convective mixing in winter, which causes a large planktonic bloom in spring (Kessouri et al., 2018; Mayot et al., 2017).

Large rivers are absent along the Portuguese coast south of Lisbon, whereas the Guadiana and Guadalquivir rivers discharge water at annual mean rates of $180 \text{ m}^3 \text{ s}^{-1}$ and $230 \text{ m}^3 \text{ s}^{-1}$.

¹ on average, respectively, into the Gulf of Cadiz, which connects surface-flowing North Atlantic waters with the Mediterranean waters flowing at depth (Fig. 1). To the east, the annual mean river discharge of each minor European and African river ranges between 5 and 50 m³ s⁻¹ to the Alboran Sea (Struglia et al., 2004). The annual mean fluvial discharge across the Western Mediterranean catchment area increases towards the northeast, with African rivers contributing each between 5-150 m³ s⁻¹ to the Algerian Basin and major annual mean contributions from the Ebro River (300-500 m³ s⁻¹) and the Rhone River (1500-1800 m³ s⁻¹) draining into the Balearic Sea and the Gulf of Lions, respectively (Fig. 1) (Struglia et al., 2004). Like most rivers with large drainage basins (Blair & Aller, 2012), the Ebro and the Rhone rivers transport and deliver large amounts of pre-aged and petrogenic terrestrial OC eroded from sedimentary rock outcrops, which for these rivers are mainly composed of sandstone, limestone and shales (Ollivier et al., 2010; Soria-Jáuregui et al., 2019). Offshore sediment dispersal from the Ebro River is limited to the broad continental shelf of the Balearic Sea (Arnau et al., 2015), whereas sediments delivered by the Rhone River might be intercepted by canyons and transported to the deeper basin of the Gulf of Lions and along the continental margin of the Balearic Sea (Palanques et al., 2006).

Previous studies have addressed the influence of other local-scale processes and features on the fate of OM in this region. For instance, lateral transport of fine-grained sediments via intermediate and bottom nepheloid layers has been suggested to contribute to the dispersal and geochemical signature of OC in the SW Iberian margin (Magill et al., 2018). Submarine canyons incising the European margin play a major role channelling sediments resuspended from the shelf towards the deeper basins. The most prominent canyon in the south-western basins is the Almeria Canyon, affected by active tectonics and characterized by downslope processes (García et al., 2006). Yet, canyons are more abundant and developed towards the northeast (Canals et al., 2013) where they channel shelf sediments resuspended by storms and coastal processes (e.g., wave activity and local outfalls) basinward (Quirós-Collazos et al., 2017), leading to the preferential off-shelf export of fine-grained sediments enriched in OC (Pedrosa-Pàmies et al., 2013). Sediments are drained by canyons to the deep basin by sediment gravity flows. The latter mainly include turbidity currents, as observed in the Valencia Trough (Amblas et al., 2011; O'Connell et al., 1985), but also dense shelf water cascading, as in the Gulf of Lions (Durrieu de Madron et al., 2023). Here, intense winter storms coupled with the overflow of cold, dense-shelf waters that are channelled through submarine canyons, drive large volumes of eroded sediment and aged OC towards the deep-sea (Canals et al., 2006; Tesi et al., 2010), although the OC signal of these events on the slope is masked by the intrinsic heterogeneity of surface sediments (Durrieu de Madron et al., 2020).

Finally, bottom trawling activity performed on the margin down to 1000 m depth is also responsible for grain size sorting and modifies OM composition (Paradis et al., 2021a). Such activity triggers sediment gravity flows into submarine canyons (Puig et al., 2012) that may form persistent nepheloid layers (Arjona-Camas et al., 2021) that also affect OM signature that is transported towards the deep sea (Paradis et al., 2022).

Figure 1. Study area and location of the 149 surface sediment samples. Surface and deep water circulation is marked by solid and dashed arrows, respectively. Coloured symbols indicate sampling location and coring device used. The Mediterranean Sea is divided into smaller basins following Bricaud et al. (2002).

3. Methods

3.1. Sample description

A total of 149 core-top samples were analysed: 134 from the Western Mediterranean Sea and 15 from the adjacent Atlantic Ocean, west of the Strait of Gibraltar (Fig. 1 and Table S1). The samples were retrieved at water depths ranging from 18 to 4672 m during several oceanographic cruises carried out between 1979 and 2011 using a variety of coring devices (gravity corer, piston corer, kasten corer, box corer, and multicorer). Multicore and box core samples were sliced onboard at 0.5 or 1 cm and kept at 4°C until the return to the laboratory. Sediment cores, on the other hand, were stored at the Core Repository of the Institute of Marine Sciences (CSIC) in Barcelona until sampling of the top cm (0–1 cm) for this investigation. All sediments were stored at -20 °C in different laboratories and freeze-dried prior to analyses.

3.2. Radiocarbon analyses

Samples analysed for radiocarbon ($^{14}\text{C}/^{12}\text{C}$) were measured as CO_2 gas in a Mini Carbon Dating System (MICADAS) with a gas ion source at the Laboratory of Ion Beam Physics, ETH Zürich.

For $\text{OC-}^{14}\text{C}$ analyses, between 20–25 mg of freeze-dried and homogenized sediment were fumigated in silver capsules with concentrated HCl (37 %, 72 h) to remove inorganic carbon and subsequently neutralized under basic atmosphere (NaOH pellets, 72 h) in a desiccator at 60 °C. Samples were wrapped in tin capsules and $\text{OC-}^{14}\text{C}$ was determined by Elemental Analyzer–Accelerator Mass Spectrometry (EA–AMS). Processing blanks, consisting of fossil (in-house shale) and modern (in-house sediment) reference materials were prepared following the same procedure. The oxalic acid reference material (NIST SRM 4990C) was used as normalization standard. The method proposed in Welte et al. (2018) was adopted to assess and correct for capsule contribution and constant contamination introduced during sample fumigation and EA–AMS measurements. The estimated correction parameters were a carbon mass of $6.3 \pm 1.6 \mu\text{g}$ with a $F^{14}\text{C}$ of 0.65 ± 0.19 . These values are higher than the long-term mean of the ETH laboratory (2–3 $\mu\text{g C}$). The source of contamination was not investigated, nevertheless, all the samples were prepared as large samples ($>100 \mu\text{g C}$), the subsequent correction did not substantially modify the $F^{14}\text{C}$ values, and the error associated to the corrected values is $< 2\%$ for most samples.

Planktic foraminifera- ^{14}C was used as an indication of the age of surface sediments. Unlike OC bound to fine minerals, planktic foraminifera are large and dense, and thus less prone to resuspension and redistribution. Approximately 3 g of freeze-dried sediment from 27 samples were wet-sieved with tap water through 63- and 150- μm mesh sieves and thoroughly washed with deionized water prior drying at 60 °C overnight. Well-preserved tests of *Globigerina bulloides*, *Neogloboquadrina incompta* or *Globorotalia inflata* were collected to determine ^{14}C from 40–100 μg of C using an automated method for acid digestion of carbonates (Wacker et al., 2013). ^{14}C determinations were corrected for isotopic fractionation via $^{13}\text{C}/^{12}\text{C}$ isotopic ratios.

^{14}C data for OC and foraminifera are reported here in $\Delta^{14}\text{C}$ notation (Stuiver & Polach, 1977).

3.3. ^{210}Pb analyses

Only a subset of 29 samples had sufficient material for excess ^{210}Pb analyses, which was used to determine the recent ($< \sim 100$ yr) deposition of sediment in core-tops following Sánchez-Cabeza et al. (1998) at the Autonomous University of Barcelona. Briefly, 200–300 mg of homogenized sediment was microwave-digested using concentrated HF,

HNO₃, and HBO₃, using ²⁰⁹Po as an internal tracer. The resulting solutions were evaporated and reconditioned with 1 M HCl. Polonium isotopes were spontaneously deposited onto silver disks while stirring at 70 °C for 8 h. Alpha emissions of ²⁰⁹Po (4883 keV) and ²¹⁰Po (5304 keV) were quantified using passivated implanted planar silicon (PIPS) detectors (CANBERRA, model PD-450.18 A.M.) and the Genie™ data acquisition software. Concentrations of ²¹⁰Po were then transformed into total ²¹⁰Pb concentrations assuming secular equilibrium of both radionuclides at the time of analysis. Excess ²¹⁰Pb concentrations were obtained by subtracting total ²¹⁰Pb from supported ²¹⁰Pb concentrations, the latter obtained from data of sediment cores in the area (Martín et al., 2014; Masqué et al., 2002; Paradis et al., 2018).

3.4. Stable isotopic and elemental analyses of OM

Organic carbon content (dry weight; OC%) was measured simultaneously with OC-¹⁴C on the same aliquots by EA–AMS (section 2.2.) to an accuracy of better than 0.1 % based on standards.

Between 10 and 15 mg of freeze-dried and homogenized sediment were fumigated as described for OC% and OC-¹⁴C to determine stable carbon isotopic composition ($\delta^{13}\text{C}$) on an EA coupled in continuous flow with a Delta V isotope ratio mass spectrometer (EA-iRMS). Values are reported relative to the Vienna Pee Dee Belemnite and precision was better than 0.1 ‰ (1 σ) based on replicate measurements of standards. For total nitrogen content (N%) and stable nitrogen isotopic composition ($\delta^{15}\text{N}$), approximately 30 mg of freeze-dried and non-decarbonated sediment were analysed via EA-iRMS. $\delta^{15}\text{N}$ values are reported relative to N₂ in air. The atomic C/N ratio was then calculated using N% and OC%.

3.5. Grain size and mineral SA

For grain-size and SA estimates, freeze-dried sediments were combusted (450 °C, 12 h) to remove OM and cooled down slowly (50 °C per hour) prior to analyses.

Between 1-2 g of combusted sediment were suspended in a solution of sodium hexametaphosphate in Milli-Q® water (1 g L⁻¹) and analysed via laser diffraction on a Mastersizer 2000. Samples were measured in triplicates under conditions of repeatability. Results were analysed in terms of clay (<2 μm), fine silt (2-10 μm), coarse silt (10-63 μm), and sand (>63 μm).

Between 150-500 μg of combusted sediment were used for the analyses of nitrogen-based BET (Brunauer–Emmett–Teller) surface area on a Quantachrome NOVA 4000e. Degassing was performed with a Quantachrome FLOVAC degasser at 350°C for 2 hours. Precision of low- and high- surface area measurements was $\geq \pm 0.04 \text{ m}^2 \text{ g}^{-1}$ and $< \pm 1.00 \text{ m}^2 \text{ g}^{-1}$, respectively, based on replicate measurements of surface area Quantachrome instruments standards.

4. Results

4.1. Radiocarbon content and ages

Bulk OC- $\Delta^{14}\text{C}$ ranges from -130 to -970 ‰ (-462 ‰ on average) and features large spatial variability (Fig. 2a and Table S2). Generally, values decrease from the southwest to the northeast, except for the Gulf of Lions, where several samples show intermediate values. The most ¹⁴C-depleted samples (i.e., the oldest OC) are found in the Algero-Provencal Basin (-526 to -970 ‰) and the Gulf of Lions (-503 to -695 ‰). The most ¹⁴C-enriched

values (i.e., the youngest OC) are found in the Atlantic sector (-235 to -390 ‰) and in the Alboran Sea (-195 to -753 ‰). In the Atlantic sector, the more ^{14}C -depleted values in the Gulf of Cadiz contrast with higher $\Delta^{14}\text{C}$ values off the west coast of Portugal. Similarly, samples from the Catalan continental shelf show higher values than those observed in the Valencia Trough.

Conventional (uncalibrated) ^{14}C ages of planktic foraminifera samples range between 500 and 17,470 yr BP (Fig. 2c and Table S2). Incorporation of bomb ^{14}C in two samples in the Alboran Sea indicates foraminifera tests originated after the radiocarbon thermonuclear weapon testing in the 60s'. By contrast, four samples in the Balearic Sea and Algero-Provencal Basin show ^{14}C ages >10,000 yr.

Figure 2. Spatial distribution of sample ages. (a) Radiocarbon content of OC, (b) radiocarbon age of OC, (c) radiocarbon age of planktic foraminifera, (d) excess ^{210}Pb in sediments, and (e) age difference between OC and planktic foraminifera. Note the non-linear colour scale in (b)-(e) to avoid masking of lower values. White circles in panels (c) and (e) represent incorporation of bomb ^{14}C and negative age differences, respectively. Note some sample locations overlap (Table S3).

4.2. Excess ^{210}Pb concentrations

Samples from the Alboran Sea show highest excess ^{210}Pb concentrations, between 112 and 665 Bq kg⁻¹ (Fig. 2d). In the Balearic Sea and Gulf of Lions, only the samples from depths < 1800 m have detectable excess ^{210}Pb concentrations (28-115 Bq kg⁻¹), whereas deeper water samples have undetectable excess ^{210}Pb . Similarly, the two analysed samples from the Algerian Basin do not have any detectable excess ^{210}Pb .

4.3. OM content and properties

The OC% values range from 0.1 to 1.9 % (Fig. 3a and Table S2). The highest values are found in the Atlantic sector and Alboran Sea (0.83 % and 0.79 % on average, respectively) decreasing throughout the Algerian Basin (0.78 %), the Balearic Sea (0.71 %), and the Algero-Provencal Basin (0.40 %). Values in the Gulf of Lions increase up to 0.64 % on average.

The $\delta^{13}\text{C}$ values range from -21.8 to -27.1 ‰ and show a general decreasing trend towards the northeast, except for the higher values observed in the Gulf of Lions (-22.7 ‰ on average) (Fig. 3b and Table S2). Accordingly, minimum values are found in the Algero-Provencal Basin (-23.8 to -27.2 ‰) while the highest values are found in the Atlantic sector (-22.7 to -23.6 ‰).

Figure 3. Spatial distribution of isotopic and elemental composition of OM. (a) OC content (wt%), (b) stable carbon isotopic composition, (c) total nitrogen content, (d) stable nitrogen isotopic composition, and (e) atomic C/N ratio, with non-linear colour scale to avoid masking of lower values. Data from 13 samples in the Gulf of Lions in panels (a)-(d) are reported elsewhere (Durrieu de Madron et al., 2020).

N% values range between 0.02 and 0.17 % and show a gradual southwest to northeast decrease (Figure 3c and Table S2) with minimum values in the Algero-Provencal Basin and Gulf of Lions (0.05 and 0.07 % on average, respectively). The prodelta areas of the Ebro and Llobregat rivers in the Balearic Sea show slightly higher N values than surrounding samples.

The $\delta^{15}\text{N}$ values range from 1.8 to 5.8 ‰ and, except for the Gulf of Lions, show an apparent SW-NE decreasing trend (Fig. 3d and Table S2). Surface sediments from the Ebro shelf are enriched by 1 ‰ with respect to nearby sediments.

C/N ratios range from 3.2 to 25 and show a spatially variable distribution within the different basins (Fig. 3e and Table S2). In general, the lowest values are found in the Atlantic sector (6.7-9.3), the Algerian Basin (3.1-15.6), and the Alboran Sea (5.5- 9.8), excluding two outliers with a C/N ratio of 25. In contrast, Balearic Sea and the Algero-Provencal basin show more variable and higher values (5.0-27.2). Samples within the Ebro shelf reveal lower C/N values (~5) than surrounding sediments on the adjacent shelf. The Gulf of Lions shows lower variability (8.9 to 14.7) and the highest average value (10.5).

4.4. Sedimentological properties

Median grain-size values range between 5 and 384 μm (Fig. 4a and Table S3). Most samples are mainly composed of silt, with coarse (10-63 μm) and fine silt (2-10 μm) being the greatest contributors (35 and 39 % on average, respectively) (Fig. 4b-e and Table S3). Grain-size composition is rather homogeneous in the southern region (Atlantic sector, Alboran Sea, and Algerian Basin) with relatively high percentages of total silt (56-88 %). The total silt contribution increases towards the northeast along with a slight increase in the median grain size.

Mineral SA ranges from 1.6 to 44.7 $\text{m}^2 \text{g}^{-1}$ with a mean of 18 $\text{m}^2 \text{g}^{-1}$ and shows an apparent decrease towards the northern basins (Fig. 4f and Table S3).

Figure 4. Grain-size composition. (a) Median grain size with non-linear colour scale to avoid masking of lower values. relative abundance of: (b) clay, (c) fine silt, (d) coarse silt, and (e) sand. (f) Mineral surface area and (g) OC loadings normalized to mineral surface area.

5. Discussion

5.1 Sedimentation rates and possible artefacts during core recovery

Low sedimentation rates typically imply lower $\text{OC}-\Delta^{14}\text{C}$ as sediment mixing entrains older carbon from deeper sediment layers. The observed decreasing trend in $\text{OC}-\Delta^{14}\text{C}$ values corresponds with major changes in sedimentation rates across the study area. For instance, sediment accumulation rate is highest in the Alboran Sea (~0.1 cm/yr; Masqué et al., 2003) and decreases towards the Balearic Sea (~0.05 cm/yr; Zuo et al., 1997) and the Gulf of Lions as a function of water depth (0.01-0.65 cm/yr; Miralles et al., 2005). The lowest values are observed in the Algerian basin (0.008 cm/yr; Jimenez-Espejo et al., 2007).

In this regard, the possible partial loss of surface sediments during core recovery would have a larger impact on measured core-top ages in the north-eastern basins. Many of the oldest samples were retrieved by kasten coring (Fig. 1), which, if used correctly, and unlike gravity coring, typically leads to high recoveries of the top few centimetres of the sediment column (Gersonde & Seidenkrantz, 2013). By contrast, box coring and multicoring are assumed to faithfully recover the sediment-water interface. Excess ^{210}Pb is typically used as an indicator of recent sedimentation (< 100 yr). However, the time elapsed between core retrieval and ^{210}Pb measurements (40-30 yr in most cases) limits the detection of excess ^{210}Pb to sites where high concentrations occurs naturally (i.e., Atlantic sector, Alboran Sea, and possibly some locations of the Balearic Sea, in agreement with observations (Fig. 2d)).

Samples from the Gulf of Lions retrieved by multicorer between 2008 and 2011 (Table S1) represent only the top half-cm of a multicore (0-0.5 cm) and yet, ages range between 2,370 and 9,470 ^{14}C yr (3660 ^{14}C yr, on average) indicating the presence of strongly aged

OC even in freshly deposited sediment layers in this region. This finding supports the consistency of the ^{14}C age decrease towards the north-eastern basins regardless of the employed coring device. Moreover, our results are consistent with evidence from three sediment traps deployed in this region that recorded highly depleted OC- $\Delta^{14}\text{C}$ values (from -653 to -774 ‰) and old ages ($\sim 8,500$ to $\sim 12,000$ yr) in the water column (Tesi et al., 2010). These results were attributed to the resuspension and subsequent transport of sediments buried in the upper slope containing fossil OC.

Potential sediment loss during coring also does not explain the large age discrepancies observed between co-deposited foraminifera and OC for these samples, which range from hundreds to several thousands of years (Fig. 2e, Table S2). Older-than-foraminifera OC ages are typically interpreted as resulting from transport of pre-aged/fossil OC to the study site (e.g., Mollenhauer et al., 2005; Ohkouchi et al., 2002). OC is older than foraminifera in most of the samples, and the magnitude of this discrepancy increases towards the NE, supporting the idea that the input of pre-aged/fossil OC is higher in this region. Two samples in the NE show younger-than-foraminifera OC ages (Fig. 2e), a phenomenon typically ascribed to post-depositional processes like bioturbation (Ausín et al., 2019). Values of surface mixed layer depth are spatially distinct in the NE, ranging from high (up to 30 cm) near the Rhone and down to <0.5 cm offshore (Zuo et al., 1997), where these two samples are located. Yet, additional factors like decreased foraminifera production, shell fragmentation, or lateral displacement of foraminifera tests by strong currents may have contributed to the magnitude of the observed negative age differences in these two samples (ca. 10,000 ^{14}C yr).

Overall, while potential sediment loss in some samples cannot be discounted, such potential artefacts cannot explain the geochemical gradients that emerge from these data (Fig. 5), which are indeed coherent with the main biological, hydrological, and sedimentological changes that occur along the ^{14}C age gradient (section 5.3). Thus, an interplay of factors including lower vertical flux of fresh OM, lower sedimentation rates, and higher input of fossil and pre-aged OC by rivers and re-exposed sediments may have determined the observed geochemical and sedimentological spatial patterns.

5.2. Geochemical and sedimentological spatial patterns

An apparent SW-NE gradient is observed in most of the geochemical and sedimentological features (Figs. 5a-h), which generally show a decreasing trend towards the north-eastern basins. However, an exception to these trends is found in samples collected from the Gulf of Lions. In this region, a notable trend reversal is observed in most parameters, as illustrated in figures 5a-e and g.

Figure 5. Boxplot of the main geochemical and sedimentological characteristics of OM within each basin, shown from the SW to the NE of the study area. (a) OC content (wt%), (b) nitrogen content, (c) stable carbon isotopes of OC, (d) stable nitrogen isotopes, (e) radiocarbon content of OC, (f) mineral surface area, (g) clay and (h) coarse silt relative abundance. Black dots represent the values for each sample. The solid black line is the median and the upper and lower limits of the box represent the interquartile range (25 % - 75 %). Open circles indicate potential outliers.

Specifically, samples from the south-western basins (i.e., the Atlantic sector and Alboran Sea) exhibit higher median OC% and N%, higher median $\delta^{13}\text{C}$, $\delta^{15}\text{N}$, and $\Delta^{14}\text{C}$ values, and higher median mineral SA and relative abundance of clay than the Balearic Sea and the Algero-Provencal Basin.

5.3. Major biological and hydrological controls on the spatial distribution of the geochemical characteristics of OM

The spatial variability observed in the elemental and stable isotopic composition of OM indicates regional differences in the relative proportions of marine and terrestrial OM (Rau et al., 1989; Wada & Hattori, 1991). These, in turn, reflect the major biological and hydrological processes that characterize the study area. For instance, the spatial gradient in OC% (Fig. 5a) parallels that of primary productivity as evidenced by ocean colour satellite data (Bosc et al., 2004; D'Ortenzio & Ribera d'Alcalà, 2009) and model analysis (Colella et al., 2016; Lazzari et al., 2012).

In the south-western basins (Atlantic sector and Alboran Sea), higher OC% can be largely explained by enhanced vertical settling of local and freshly produced OM. In agreement, sedimentary OC from these basins is of primarily marine origin and relatively young (higher OC- $\Delta^{14}\text{C}$ values) (Fig. 6a). Here, higher $\delta^{13}\text{C}$ and lower C/N values agree with typical values of marine phytoplankton for northern mid-latitudes (-20 and -22.5 ‰ (Verwega et al., 2021) and ~ 7 (Liang et al., 2019; Meyers, 1994), respectively). The Atlantic sector is part of a major upwelling region, whereas the primary production in the Alboran Sea is one of the highest in the Mediterranean Sea (Lazzari et al., 2012). Moreover, the major rivers in this region have smaller drainage basins and lower discharge volumes in relation to the major northern rivers (Ebro and Rhone), and except for the Almeria canyon, canyons are not as well developed in this southern region (Würtz, 2012). Altogether, these factors diminish the potential input of terrestrial OC.

Figure 6. Isotopic composition of OM. (a) Radiocarbon content versus $\delta^{13}\text{C}$ with OC content as normalized bubble size, and (b) $\delta^{13}\text{C}$ versus $\delta^{15}\text{N}$ with atomic C/N ratios as normalized bubble size. Dashed boxes indicate the main endmembers: marine phytoplankton (Verwega et al., 2021), soil OM (McCallister et al., 2004; Ogrinc et al., 2008), and dominant Mediterranean vegetation (C3 plants; Countway et al., 2007; Hedges et al., 1997; Ogrinc et al., 2008).

By contrast, the OC content gradually decreases and ages towards the NE (Fig. 6a). This pattern is explained by reduced primary productivity and increased input of terrestrial OM throughout the Algerian Basin, the Balearic Sea, and the Algero-Provencal Basin. Resuspension and lateral transport of fine sediments by strong deep currents can expose mineral-associated OC to further alteration, leading to the preferential degradation of more labile (younger and predominantly marine) OC in relation to the more refractory (older material including terrestrial) OC (Bao et al., 2016; Tesi et al., 2007). However, the observed extremely low $\Delta^{14}\text{C}$ values (-381 to -970 ‰) cannot solely be explained by ageing during resuspension and lateral transport. These values instead likely indicate the input of fossil/petrogenic (^{14}C -depleted) OC, mainly of terrestrial origin (Fig. 6b). Indeed, numerous rivers discharging into this region are responsible for the entrainment of large amounts of terrestrial OM in the north-eastern basins. The biochemical characterization over a 1 year period of the particulate OM delivered by 8 major and minor rivers discharging into the Gulf of Lions and the Catalan shelf showed $\delta^{13}\text{C}$ values ranging from -33 to -24.5 ‰, $\delta^{15}\text{N}$ values between 1.9 and 16.8 ‰, and C/N values from 2.8 to 14.7 (Higuera et al., 2014). According to Higuera et al. (2014), such values reflect the admixture of soil OM (McCallister et al., 2004; Ogrinc et al., 2008) and vascular C3 plant remains (Countway et al., 2007; Hedges et al., 1997; Ogrinc et al., 2008).

Weathering and supply of terrestrial OC to the Balearic Sea by the Rhone and Ebro rivers is typically limited to the shelf (Arnau et al., 2015; Palanques et al., 2006). However, the

presence of large submarine canyons on the Catalan shelf compared to the margins of the south-western basins and the seaward deflection of the coastal current at the southern limit of the Valencia Trough (Fig. 1) deliver large quantities of sedimentary OM to deeper waters (Arnau et al., 2015; Ulses et al., 2008). Similarly, fish trawling activity, which influences sedimentary OM distribution through sediment erosion and enhanced OC remineralization (Palanques et al., 2014; Paradis et al., 2021b), is limited to the shelf and upper slope of the Catalan margin. Nevertheless, onshore and offshore $\delta^{13}\text{C}$ values are comparable (Fig. 3b), suggesting the input of terrestrial OC through mass movement events and strong along-slope and upslope currents around the Balearic Island (Lüdmann et al., 2012) and the efficient transport of sedimentary OM along the basin in the Valencia Trough (Amblas et al., 2011; O'Connell et al., 1985). Slightly enhanced $\text{N}_\%$ and $\delta^{15}\text{N}$ values in the proximity of the mouth of the Ebro River have been ascribed to the delivery of synthetic fertilizer products derived from agricultural activities (Lassaletta et al., 2012), enabled by the dense irrigation channels and reservoirs in the catchment area of the Ebro ($<400 \text{ kg N km}^{-2} \text{ yr}^{-1}$) (Romero et al., 2016).

In the Gulf of Lions, relatively higher $\Delta^{14}\text{C}$ and $\delta^{13}\text{C}$ (Fig. 6a) values reflect higher contribution of marine OM linked to increased primary productivity compared to other north-eastern basins of the NW Mediterranean Sea (Bosc et al., 2004; Colella et al., 2016; D'Ortenzio & Ribera d'Alcalà, 2009). $\Delta^{14}\text{C}$ and stable isotopic values of OM agree with previous observations and suggest the admixture of OC from different sources (Sanchez-Vidal et al., 2009; Tesi et al., 2010). In addition to the intense seasonal planktonic bloom that characterizes this region, fluvial discharges by major and minor rivers imply the entrainment of large amounts of terrestrial OC (Higuera et al., 2014). Previous work has shown the alternation between sedimentary OC sources in the Gulf of Lions, being predominantly terrestrial during winter, and mainly marine during spring and summer (Sanchez-Vidal et al., 2009). Re-exposure and advection of sediments deposited during low sea-level stands and buried on the upper continental slope are an additional source of pre-aged/fossil OC in this region (Tesi et al., 2010). Finally, resuspension and dispersal of sediments by deep currents following bottom-reaching convection events in this region (Durrieu de Madron et al., 2017; Stabholz et al., 2013) further contributes to the mixing of freshly produced marine OM and older terrestrial OM (Canals et al., 2006; Sanchez-Vidal et al., 2009).

5.4. Potential additional controls on the distribution and fate of OM via organo-mineral associations

5.4.1. Lateral transport of allochthonous OC

Substantial and positive age differences between co-deposited OC and planktic foraminifera increase towards the NE and are mainly ascribed to the addition of old OC (sec. 5.1). Whereas the origin of this OC appears to be predominantly terrestrial, the contribution of laterally transported pre-aged/fossil OC of marine origin in association with mineral grains has been observed in the region (Tesi et al., 2010) and could have contributed to the observed age differences to some extent.

Moreover, OM may age during resuspension/redeposition cycles (Bao et al., 2016) because selective degradation of the more labile organic molecules over the more refractory material occurs under oxic conditions and lateral transport leads to an increase in oxygen exposure times (Burdige, 2007; Hedges et al., 1999). Recently produced marine OM is more prone to remineralization potentially as a consequence of its chemically labile and less altered nature compared to terrestrial OM (Zonneveld et al., 2010). Similarly,

previous work in the Gulf of Lions has shown that sedimentary OM along a mud belt on the shelf is much more depleted in ^{14}C than in the delta region due to the preferential loss of labile OM and retention of fossil carbon during resuspension and lateral transport (Cathalot et al., 2013; Tesi et al., 2007). Thus, preferential degradation of freshly produced marine OC could have also contributed to the observed terrestrial signal towards the NE basins.

Finally, hydrodynamic mineral sorting during lateral transport leads to a strong ^{14}C age-grain-size dependence (Ausín et al., 2021). The spatial changes observed in the relative contribution of clay and sortable silt (Figs. 5g, h) suggest that hydrodynamically-sorted minerals that host OC could contribute to some extent to the observed $\Delta^{14}\text{C}$, which decreases towards the NE (except in the Gulf of Lions) along with a decrease in clay relative abundance and an increase in coarse silt percentage. Yet, and as in other marginal seas, no apparent relationship is observed between $\Delta^{14}\text{C}$ and median grain size in samples dominated by fine-grained sediments ($<63\ \mu\text{m}$, fig. 7a) because the $\Delta^{14}\text{C}$ -grain-size relationship is only apparent when investigated across grain-size fractions (Bao et al., 2016).

5.4.2. OM protection via association with mineral surfaces

Minerals influence the abundance and geochemical composition of sedimentary OC via mineral SA protection (Keil et al., 1994). Finer mineral grains offer higher SA (Fig. 7b); spaces where the OM may be occluded and OC is protected from remineralization by heterotrophic organisms (Bianchi et al., 2018). Accordingly, OC preservation would be comparatively lower in the Balearic Sea and Algero-Provencal Basin (Figs. 5f and 7b) because lower SA would expose OM to selective degradation (Zonneveld et al., 2010).

SA does not follow the SW-NE gradient observed in other geochemical and sedimentological parameters because it is not the highest in the Atlantic side. The latter suggest a lower potential for OM protection by mineral surfaces in the Atlantic sector. However, the OC/SA ratio allows the assessment of net supply and reaction processes of OC and preservation efficiency (Blair & Aller, 2012). Most OC/SA values are $< 0.4\ \text{mg C m}^{-2}$ (Fig. 7c). This is especially the case for the majority of the samples from the Algerian Sea, Balearic Sea, and Algero-Provencal Basin, with few exceptions from shallower waters from the Balearic Sea that show an OC/SA ratio between 1 and $0.4\ \text{mg C m}^{-2}$. OC/SA values $< 0.4\ \text{mg C m}^{-2}$ are characteristic of passive continental margins and environments where sediment is frequently resuspended and subjected to enhanced remineralization (e.g., highly energetic deltaic deposits and low-sedimentation-rate deep-sea environments with long oxygen exposure times) (Bao et al., 2018; Blair & Aller, 2012). Samples from the Atlantic Sector and the Alboran Sea, on the other hand, show comparatively higher OC/SA values, and more than half of them show ratios in the $1\text{-}0.4\ \text{mg C m}^{-2}$ range. These values are characteristic of river-suspended material and shelf sediments and indicate relatively stable OM-mineral associations that prevent OC from further remineralization (Blair & Aller, 2012; Hedges & Keil, 1995). Therefore, our results suggest that the potential for OM protection by mineral surfaces is larger in the Atlantic sector and Alboran Sea, and lower in the Balearic Sea and Algero-Provencal Basin. In the absence of other factors that have also proven to play an important role in OM protection like sediment mineralogy (Blattmann et al., 2019), mineral surface area protection would magnify the observed geochemical gradients.

Figure 7. Additional controls on the distribution and fate of OM. (a) Relationship between $\Delta^{14}\text{C}$ and median grain size with coarse silt ($10\text{-}63\ \mu\text{m}$) relative abundance as

normalized bubble size, (b) relationship between mineral surface area and median grain size, and (c) OC content vs mineral surface area with water depth as normalized bubble size. FS=Fine silt. CS=Coarse silt. Solid lines in (b) indicate OC/SA ratios >1 and <0.4 mg OC m⁻², which allow the differentiation of depositional environments (Bianchi et al., 2018; Blair & Aller, 2012).

6. Conclusions

Figure 8. Conceptual model summarizing the influence of major and potential additional controls on the geochemical characteristics of sedimentary OM in the Western Mediterranean Sea and adjacent Atlantic sector, from the SW to the NE. Values of the main geochemical parameters correspond to the bound mean values (10 %) of each basin. Note the SW-NE gradient, which reverses in the Gulf of Lions.

This regional study on the isotopic and elemental composition of OM in surface sediments from the western Mediterranean Sea and the neighbouring Atlantic sector west of the Strait of Gibraltar sheds light on the controls on the origin, distribution, and fate of OM in continental margins and adjacent deep-sea basins.

Here, most geochemical parameters depict a clear SW-NE gradient that reverses in the Gulf of Lions (**Fig. 8**). Thus, samples from the Atlantic sector and Alboran Sea reveal comparatively younger OM that is primarily of marine origin. Samples from the Algerian Basin, the Balearic Sea, and the Algero-Provencal Basin exhibit a larger influence of terrestrial OC towards the NE characterized by lower $\delta^{13}\text{C}$ and ^{14}C values. OM in the Gulf of Lions shows a more prominent influence of fresh and young OC compared to other basins in the north-eastern part of the NW Mediterranean Sea. Such spatial variability largely reflects regional differences in relation to marine primary productivity and terrestrial input of pre-aged/fossil OC, the latter delivered by rivers and channelled to the deeper basin by the numerous canyons that incise the continental margin, especially towards the NE of the study area.

When explored from a sedimentological context, our results reveal the potential secondary control of two other mechanisms on the fate of OM (**Fig. 8**). The first involves the resuspension and lateral transport of allochthonous (mainly pre-aged or fossil) OC in association with fine-grained sediments. The increasing contribution of coarse silt towards the NE basins suggests the impact of this mechanism is potentially greatest in the north-eastern basins, where intense high-energy events promote grain-size sorting and its subsequent sediment (and OC) redistribution. Moreover, lateral transport would further expose OM to oxic conditions, favouring selective degradation of labile OC over refractory OC. The other potential secondary control in the fate of OM is OM protection from oxic degradation via association with mineral surfaces. This mechanism would have a larger influence in the Atlantic sector and Alboran Sea according to comparatively higher OC/SA ratios in these basins. In the Balearic Sea and Algero-Provencal Basin, lower OM protection by mineral surfaces would potentially lead to lower OC% and the preferential retention of more refractory terrestrial OC that renders bulk OC strongly depleted in ^{14}C , in line with the observed geochemical gradients.

Overall, the spatial heterogeneity exhibited by the western Mediterranean Sea allows us to explore the interplay of biological, chemical, and hydrological factors that control the amount and geochemical characteristics of sedimentary OM in continental margins, including the land-sea continuum and the deeper ocean.

Acknowledgements

The authors are grateful to the Editors and two anonymous Reviewers for carefully reviewing this Manuscript and improving it substantially with their comments and suggestions. The authors are indebted to Daniel Montluçon from the Biogeoscience Group at ETHZ, who provided inestimable laboratory guidance during this investigation. Madalina Jaggi and the Climate Geology Group from ETHZ are acknowledged for their support in nitrogen isotope analyses. Hugo Marcos is acknowledged for doing the boxplot graphs. The authors are sincerely grateful to the Core Repository of the Institute of Marine Sciences (CSIC) at Barcelona for providing access to most of the sediments used in this study. Samples off W Portugal were collected during Cruise 089 aboard the RSS James Cook, that was made possible with support from the UK Natural Environmental Research Council (NERC Grant NE/J00653X/1). This study was supported by the project TRAMPOLINE (200021_175823) funded by Swiss National Science Foundation and the project PASSAGE (Grant agreement No 101039348) from the ERC under the European Union's Horizon 2020 research and innovation program.

Authors contribution

BA and TE planned and designed this investigation. GB processed most of the samples for most analyses and NK contributed with unpublished data. SP performed radionuclide analyses and BA processed samples for foraminifera radiocarbon analyses, which were measured by NH. XDM and B. Alonso provided surface sediment samples. BA and GB analysed the results and wrote the manuscript considering contributions from all the co-authors.

Open Research

All the underlying data needed to understand, evaluate, and build upon the reported research is in the supporting information and accessible online in the Mendeley public repository under Ausin et al. (2023) <https://doi.org/10.17632/5rvvcz5ynh.1>.
