Abstract

First-principles density-functional theory has been used to investigate equilibrium geometries, total energies, and diffusion barriers for H as an interstitial impurity absorbed in $\alpha$-Fe. Internal strains/stresses upon hydrogen absorption are a crucial factor to understand preferred absorption sites and diffusion. For high concentrations, H absorbs near the octahedral site favouring a large tetragonal distortion of the BCC lattice. For low concentration, H absorbs near the tetrahedral site minimizing the elastic energy stored on nearby cells. Diffusion paths depend on the concentration regime too; hydrogen diffuses about ten times faster in the distorted BCT lattice. External stresses of several GPa modify barriers by $\approx 10\%$, and diffusion rates by $\approx 30\%$.

INTRODUCTION AND METHODOLOGY

Hydrogen embrittlement is believed to be one of the main reasons for cracking of steel structures under stress[1–3]. High strength steels often include a ferritic core made of α-iron (body centred cubic lattice, BCC). To control and prevent the cracking of steel it is necessary to understand the chemical and physical properties of hydrogen inside BCC iron. In particular, it has been argued in the literature that the size of the interstitial H (e.g. \( \approx 0.3\text{–}0.4 \text{Å} [4] \)) is too large to fit and diffuse easily in the iron BCC lattice[5]. This argument has also been used to favour absorption on the T-site because it is larger than the O-site[6]. Arguments based in ‘apparent’ sizes of atoms and a static lattice yield an useful basic approximation but leave out important factors. Only a truly microscopic understanding of hydrogen dissolved in iron, including diffusion processes and fully accounting for forces and stresses inside the host matrix could lead to answers to the many questions arising from experiments. Internal stresses are therefore key to understand the preferred absorption site. Furthermore, external stresses can be used to modify diffusion barriers because can help to stabilize/de-stabilize strains originated inside the material to accommodate the absorbed impurity. Owing to its interest, hydrogen absorbed in iron has been studied from different approaches, both from a theoretical and experimental point of view. Unfortunately, a clear consensus about fundamental questions, like the nature of the equilibrium absorption site, the reasons for H to prefer some regions over others, or how to modify the diffusion barriers has not been reached yet. Many theoretical papers have favoured hydrogen absorbed in the tetrahedral site (T)[7–12], some have preferred the octahedral one (O)[13], others have reported that they are almost equivalent[14] (Fig. 1). From an experimental point of view, it has been generally believed that hydrogen has low solubility and high mobility in bcc-iron. However, some recent experiments have attained high concentrations[15, 16], at least locally. Furthermore, experimental evidence has been reported showing that hydrogen might at least partly be found on the O-site[15]. Finally, diffusion barriers that change with the amount of H admitted into the material have been reported in the literature[17]. In our calculations, we find that both sites are indeed quite similar in energies; the delicate energetic balance between them depending on the stress distribution created by the interstitials. In turn, this depends on the hydrogen concentration, that can be related to locally inhomogeneous regions or more generally to its homogeneous averaged value.
FIG. 1: High symmetry sites for H absorption inside α-iron: the octahedral (O) and tetrahedral (T) sites (grey) are shown along with iron atoms in the BCC lattice (black).

Our methodological approach simulates the atomic absorption and diffusion of hydrogen in the body centred cubic iron lattice from first-principles. Absorption in high-symmetry sites for different hydrogen loads (densities) has been explored and the internal strains/stresses have been calculated. Diffusion barriers between these stationary absorption sites have been obtained, and the effect of external stresses on diffusion coefficients has been analyzed. Our *ab-initio* calculations are based on the Density Functional Formalism (DFT)[18] and the theory of pseudopotentials[19]. A periodic supercell is considered to minimize absorbate-absorbate interactions (periodicity is $n \times n \times n$ with respect to a single cubic BCC unit cell -UC-). One H atom has been located in this supercell, determining the ratio H:Fe from $\frac{1}{2}$ for the $1 \times 1 \times 1$ to $\frac{1}{31}$ for the $3 \times 3 \times 3$. Within this theoretical framework the accuracy of calculations mainly depend on the quality of the pseudopotential, the energy cutoff ($E_{cuf}$), and the density of the k-points mesh in the irreducible part of the Brillouin zone (a Monkhorst-Pack set of special k-points[20]). Calculations are performed with CASTEP[21, 22], where a plane-wave basis is used to expand electronic states (spin-polarized bands are considered to account for magnetism in iron). An ultrasoft pseudo-potential ($3d^6$ 4s$^2$) including a nonlinear core correction is used to describe iron atoms. The exchange and correlation contribution to the total energy is computed within a generalized gradients approximation given by Perdew, Burke and Ernzerhof[23]. An all-bands variational method is used to achieve self-consistency[24] (to improve convergence a smearing width of 0.1 eV has
been used). Minimum thresholds to consider the calculations converged after optimization of the geometry are: variations in the total energy $\leq 10^{-5}$ eV, maximum residual force on any atom $\leq 0.01$ eV, maximum residual stress on the UC $\leq 0.02$ GPa, maximum change in any atom position $\leq 0.001$ Å, and maximum change in any cell vector $\leq 0.01$ Å. These thresholds are enough for our purposes, but on some particular cases lower thresholds were considered when higher precision was desirable.

**REFERENCE CALCULATIONS FOR $\alpha$-IRON AND H**

The adequacy of the theoretical framework and the different convergence thresholds has been tested by computing a number of known properties for clean $\alpha$-iron and atomic and molecular hydrogen separately. For iron, a global energy minimum is found for a BCC lattice (hereafter referred as the $1 \times 1 \times 1$) with $a = b = c = 2.815$ Å ($\alpha = \beta = \gamma = 90^\circ$), a predicted magnetization of 2.25 $\mu_B$, a bulk modulus of 175 GPa, and a Poisson ratio of 0.30. Residual forces on the atoms in the BCC unit cell are $\leq 4 \times 10^{-6}$ eV/Å, residual stress is $\leq 9 \times 10^{-4}$ GPa, and the total energy has been converged to $\leq 10^{-6}$ eV). The computed magnitudes are to be compared with the experimental values 2.867 Å, 2.22 $\mu_B$, 170 GPa, and 0.29[25]. Fractional errors are 1.8%, 1.4%, 3%, and 4% respectively, showing the accuracy of this kind of theoretical modelling to describe relevant properties of BCC iron. It is interesting, however, to notice that these quantities show oscillatory convergence as a function of the energy cutoff ($E_{ctf}$) and the number of k-points; convergence of physical properties has to be established carefully to make sure the oscillations are damped enough as to avoid agreements that might not be stable (Fig. 2). Properly converged values were obtained with $E_{ctf} = 375$ eV and a $25 \times 25 \times 25$ Monkhorst-Pack (MP) mesh. However, values derived with $E_{ctf} = 375$ eV and a $14 \times 14 \times 14$ mesh can be considered accurate enough for our purposes and most of our calculations below for the $1 \times 1 \times 1$ BCC unit cell have been performed with these parameters. Calculations in $n \times n \times n$ unit cells ($n=2, 3$) have been performed with $4 \times 4 \times 4$ and $1 \times 1 \times 1$ MP meshes respectively. These theoretical calculations yield a detailed microscopic picture for the chemistry and the physics governing the material: iron atoms form metallic bonds of length 2.44 Å, favouring a ferromagnetic alignment of spins mostly residing in the regions around the atoms. Bonding is such that the atomic s level of iron is depopulated in favour of d and p-levels (a Mulliken analysis shows...
FIG. 2: Convergence of primitive unit cell parameter (d in Å) -upper panel-, magnetization (in units of the Bohr magneton) -middle panel-, and bulk modulus (GPa) -lower panel- versus the number of K-points in the irreducible part of the Brillouin zone (see text) and the energy cut-off (circles: 330 eV, squares: 350 eV, triangles: 370 eV).

that \(\approx 1.3\) e is transferred). Although this work is not concerned with face-centre cubic iron (\(\gamma\)-iron), we notice that this formalism predicts that the next stable phase of iron (FCC) is about 0.1 eV/atom higher in energy, with \(a = b = c = 3.479\) Å (experimental value is 3.647 Å, a 5% discrepancy), and a magnetization lower by about a factor of 2 due to disorder in
the spin orientations. Calculations for H and H$_2$ have been performed on a $10 \times 10 \times 10$ Å super-cell (only the $\Gamma$ point in the BZ), predicting a bond length and a binding energy for the molecule within 0.5% and 5% from experimental values. The interaction between isolated atoms of H and Fe is moderately weak, with a bonding distance of 1.54 Å and a binding energy of $E_B = E_{FeH} - (E_{Fe} - E_H) = -2.41$ eV (notice that the binding energy is quoted from the electronic energy alone and zero point vibrations have not been considered). This is corroborated by the very weak interaction of H with Fe$_2$; the binding energy stays nearly the same ($-2.43$ eV) in a geometrical configuration where H prefers to interact with only one of the Fe in the dimer. Molecular H$_2$ has been reported to dissociate on iron surfaces[12], in addition we do not find tendency for hydrogen atoms inside iron to re-form molecules. As an example, we compare for the $2 \times 2 \times 2$ unit cell (Fe$_{16}$H$_2$) the total energies of two H atoms located in two different octahedral sites and a single H$_2$ molecule. The dissociated state is favoured by $E_{2H} - E_{H_2} = -3.3$ eV (we notice that the energy gain comes partially from the smaller stress that two H atoms create in the iron lattice compared with the one originated from bigger single H$_2$ molecule). Therefore, we conclude that it is not necessary to study the processes related to molecular H$_2$ inside α-iron.

**HYDROGEN IN IRON: HIGH CONCENTRATION**

Even if the density of hydrogen absorbed in iron is expected to be small on the average, it can accumulate locally on some regions where the density can be high. Indeed, important changes in the elastic properties of iron are found in these regions. Furthermore, experimental evidence of high density phases have been reported in the literature[15, 16]. Therefore, we find it interesting to analyze the stoichiometry Fe$_2$H. In the BCC lattice two high-symmetry sites (O and T) compete to locate the interstitial atom, and diffusion through the iron matrix takes place along paths joining them (Fig. 1). We simultaneously optimize all the geometrical parameters to reach a global minimum in the total energy and small residual forces in any atom in the model. The three vectors defining the periodic lattice have been kept orthogonal ($\alpha = \beta = \gamma = 90^\circ$); for their modules we have compared three different cases: (a) independent optimization (resulting in tetragonal systems), (b) optimization subject to the condition $a = b = c$ (cubic system), and (c) no optimization, merely scaling the clean BCC unit cell (the system is under stress, specially for high con-
centrations of the interstitial). Starting with model (a) and allowing the lattice to relax completely, we have reached a best configuration with residual forces \( \leq 10^{-4} \) eV/Å and residual stresses \( \leq 5 \times 10^{-4} \) GPa (the energy change was \( \leq 2 \times 10^{-6} \) eV and the maximum final displacement of any atom was \( \leq 5 \times 10^{-4} \) Å). Under these conditions, the O site is the global minimum, T being higher in energy by 53 meV (Table II). To reach this configuration, the lattice suffers a large body centred tetragonal (BCT) distortion, keeping the P4/MMM symmetry group (16 elements), while the optimum geometry for the fully relaxed lattice for H in the T-site increases the symmetry from C2 (4 elements) to P-4M2 (8 elements). This result is different from the one recently obtained by Jiang and Carter using a similar methodology[12]. There are several possible sources for this discrepancy, e.g. the pseudopotentials, the exchange and correlation functional, or even the fine details of how different codes reach a self-consistent solution and compute forces on the atoms. We believe these are all unlikely sources to explain the different final configuration due to the excellent performance when comparing different physical magnitudes with experimental data or just between different theoretical methods of similar quality. Jiang and Carter predict for Fe2H that the T-site is preferred over the O-one by 10 meV, while we have found the reversed conclusion by 53 meV. The overall 63 meV discrepancy is indeed a small one, but it seems to be above the noise level expected from the convergence tests. The reason for the difference is most likely related to the final optimum configuration obtained in each calculation (our final configuration is given in Table I). The energy landscape is a complex one, and the algorithm searching for a global minimum could be trapped in nearby local ones. We have made an effort to minimize residual forces and stresses as much as possible. To search for a global minimum we have used the Broyden-Fletcher-Goldfarb-Shanno algorithm that is known to be robust and has been successfully applied both in electronic structure calculations and in Low-Energy Electron Diffraction optimization of geometries[26–28]. The resulting BCT distortion for H in the O-site is indeed quite big and might be hidden in a difficult landscape, we notice that our optimization under the restriction of an isotropic deformation of the unit cell \( (a = b = c) \) results in the T-site as the preferred one by 452 meV. Finally, we should comment that although the BCT distortion seems significant, in particular because it would favour the BCC to FCC transformation, the discussion here is based solely on electronic energies, and other factors might play an important role too. Configurational disorder is expected to favour T-sites. The relative contribution of entropy
to the Helmholtz free energy for T and O can be estimated from the simple consideration that there are four times more configurations for T-sites. Therefore, T-sites are favoured on the grounds of entropic arguments by $k_B T \log 4$, approximately 34 meV at room temperature, which tends to make the energetic more similar but still is not enough to make the T-site the global minimum. Furthermore, zero-point energy corrections (ZPE) may lower the already small diffusion barriers. A careful determination of the phonon spectra for this system demands the use of a considerable amount of computing time and is planned for a future paper. Our own initial estimates, based in sketchy models that can be solved quickly, points to a lowering of the barrier from O of $\approx 7$ meV, a lowering from T of $\approx 27$ meV, and a further stabilization of O w.r.t T by $\approx 20$ meV. A word of caution is in order here since these values may have a large error bar that we have not properly estimated. The model used to deduce these values is as follows: the cut-off energy has been reduced to 300 eV, the k-points mesh to a mere $6 \times 6 \times 5$, phonons have been estimated only in the $\Gamma$ point using a finite displacement method (0.00529 Å) and a $2 \times 2 \times 2$ super-cell. These values are only to be taken as rough order of magnitude estimates, in particular, we notice that other calculations give a correction for the barrier from the T-site of 46 meV[12]. These numbers are not enough to switch the preferred absorption site, but it is clear that after all these corrections the barrier should be lower by something between 40-50% than the one obtained purely from the electronic total energy. From a physical point of view, in this high concentration regime, the main characteristic of the tetragonal distortion necessary to accommodate H in the O-site is that it is both large and anisotropic. First, we notice that only occupation of similarly oriented O-sites over many unit cells would allow this kind of distortion. Second, fractional changes in the UC volume are large, $\frac{A}{V_o} = 0.12$, and 0.16, for O and T respectively; this is the trace of the strain tensor and measures the global stress produced by the interstitial. Therefore, it is necessary to understand the stress distribution created around the distorted cell. Total energies for a model where the UC is allowed to relax keeping the cubic UC ($a = b = c$) show that when H is in O the system gains a fair amount of energy from the anisotropic deformation (510 meV), while when H is near T the gain is smaller (9 meV). Under this cubic restriction, the fractional change of the UC volume are 0.19 and 0.16 for O and T respectively; the interstitial fits poorly in O in absence of the tetragonal distortion (internal pressure upon injection of the interstitial H in the clean iron BCC lattice amounts to several tens of GPa). From a chemical point of view, the role of the
interstitial atom is to debilitate the Fe-Fe nearest-neighbours (NN) interaction; Fe-Fe bond length increases by 0.15 and 0.08 Å for H in O and T respectively. In both sites, hydrogen tends to get negatively charged (0.3e), while its spin is delocalized contributing little to the total integrated spin density that only increases by ≈ 0.15 μB w.r.t. clean BCC Fe. It is worth to notice that the tetragonal distortion of the UC for H absorbed on the O-site (ξ = 1.38) is not far away from the distortion predicted for Bain’s mechanism to transform from α-iron to γ-iron (ξ = 1.41)[29].

To compute diffusion barriers we have used a linear synchronous-transit method followed by quadratic refinement[30]. In addition, when a reduced number of parameters could be established as the more relevant ones exhaustive searches in regions of interest have been used to display in more detail the topology around the reaction pathway (Fig. 3). We have computed diffusion barriers between the optimum configurations reached for H at O and T. For the high density case, the transition state is located in the line joining O and T, about half-way, with a barrier of B = 70 meV (Fig. 4). Thermal diffusion can be estimated by considering a typical vibrational frequency for H in the lattice: W ≈ 10^{12} Hz. Diffusion is quick, hopping from O to T happens DT(B) = 10^{11} times per second at room temperature. Quantum diffusion via tunneling through the barrier is important for such a light atom as H. The tunneling rate can be estimated from a one-dimensional WKB approximation, DQ(B, d) = We^{-\sqrt{2mHd}}, where d is the distance between minima (0.6 Å). DQ is only lower than the thermal one, DT, by a factor of 6. At low temperature, the tunneling process becomes the main mechanism, being equal in importance to the thermal one at about T ≈ 183 K, near the liquid Nitrogen temperature. The effect of external stresses on the barrier is shown in Fig. 4. A tensile stress of 2 GPa increases or decreases the barrier by about 9%; changing the thermal diffusion by about 30% at room temperature, while the quantum mechanism is affected by 25%.

HYDROGEN IN IRON: LOW CONCENTRATION AND FINITE ELEMENTS SIMULATION

We simulate the lower density scenario by placing one H in the 2 × 2 × 2 and 3 × 3 × 3 unit cells (Fe_{16}H and Fe_{34}H). At these concentrations, hydrogen is free to move around the lattice without interacting with other hydrogen atoms (the remaining H-H interaction on
FIG. 3: Total energy (meV) landscapes for (a) high and (b) low concentrations cases (top and bottom panels). O is located at the top right corner \( \left\{ \frac{1}{2}, \frac{1}{2}, 0 \right\} \), and T at the down right and top left corners, \( \left\{ \frac{1}{2}, \frac{1}{2}, 0 \right\} \). The region around the Fe at the origin (higher values than 200 meV) has been artificially put to a constant value to improve visibility of the relevant paths from O to T (a) and from T to T (b).
FIG. 4: Diffusion barriers between T-site (\(\frac{1}{2}\)) and O-site (\(\frac{1}{2}\)) along the actual diffusion path (see Fig. 3, the reaction coordinate has been scaled between both endpoints) for fully relaxed Fe\(_2\)H under different external stresses. Triangles (a) and diamonds (d) correspond to hydrostatic pressures of \(\pm 2\) GPa (tensile and compressive respectively), squares (c) to a tensile uniaxial stress of \(-1\) GPa, and circles (b) to 0 GPa. The origin of energies has always been taken as the optimum equilibrium value (for this concentration, the O-site).

the \(1 \times 1 \times 1\), \(\approx 0.06\) eV, now becomes negligible). Other convergence parameters are kept the same, except for the k-points mesh, that has been reduced accordingly to the bigger size of the super-cell. Now, the global total energy minimum still happens for a BCT lattice, but it moves from the O-site to the T-site, that becomes lower in energy w.r.t O by 119 and 105 meV for Fe\(_{16}\)H and Fe\(_{54}\)H, respectively. The change in the unit cell volume and the tetragonal distortion of the lattice gets smaller with decreasing density, and nearly independent of the absorption site, \(\Delta V / V_0 = 0.03\) and 0.004, and \(\xi = 1.04\) and 1.003 respectively (Table II). The same calculation for a relaxed BCC lattice \(a = b = c = 2.843\) Å) yields a difference of 169 meV in favour of T. Diffusion happens now from T to T with a barrier of 82 meV (BCT) or 127 meV (BCC) (Fig. 3(b)). This barrier implies a diffusion rate \(\approx 10\) times slower than for the high density case. Tunneling is even more reduced, because the distance between

minima is larger (≈ 0.9 Å). In T, H moderately interacts with four NN at 1.65 Å, and gets negatively charged by 0.33e. In O, H interacts mainly with two NN, at 1.57 Å, while the nearest next-neighbours (NNN) remain at 1.98 Å (H gets a similar amount of charge, 0.32e). Typical displacements for NN w.r.t. their positions in the clean iron lattice are ≈ 0.1 Å (NN), while NNN and more distant atoms move less than ≈ 0.02 Å. The spin on the different atoms does not show changes worthwhile to comment.

Strains to accommodate the interstitial H create a stress distribution that has been analyzed by a finite elements (FE) technique (input parameters have been obtained from our calculations above). Assuming that deformations are elastic, we have computed the stress distribution in the iron matrix and the free energy variation when H is absorbed in the O and T sites. Starting from strains obtained by DFT on the 1 \times 1 \times 1 super-cell, the FE simulation allows us to study its effect in a surrounding region of size n \times n \times n around the original volume (n = 2, 5). Strictly speaking, this procedure implies introducing a deformation field that has been computed using periodic boundary conditions on a bulk-like
TABLE III: Elastic energy distribution (meV), and fractional contribution to the total one (%) calculated by finite elements over \( n \times n \times n \) regions \((n = 2, 3, 4, 5)\). Residual energy beyond \( n = 3 \) is below a 3% of the total one.

1 \times 1 \times 1 \ cell into an infinite medium with the same elastic constants but different boundary conditions (non-periodic). This is therefore a slightly inconsistent procedure that can only be justified ‘a posteriori’ by the agreement between the energies obtained from the ab-initio calculations and the FE approach (see below).

All the FE simulations have been performed with the program Comsol Multiphysics[31], using 0.15 Å wide triangular elements. Fig. 5 gives the diagonal components of the stress tensor for H in O and T (the origin of distances is located at the surface of the deformed 1 \times 1 \times 1 \ region). Both cases show very little residual stress beyond 6 Å (which corresponds to the 3 \times 3 \times 3 \ supercell). The elastic energy distribution associated to these stresses is well converged at these distances (Table III); contributions from larger regions only amount to 1 or 2% of the total elastic energy. This result shows why it is not necessary to go beyond the 3 \times 3 \times 3 \ supercell in our ab-initio simulations. The stress distributions are very different for H in O and in T: the former is very anisotropic \((x \sim y \neq z)\) and its maximum value is \( \approx 2 \) times the maximum value for T. The stored elastic energy, quadratic on the stress tensor, is approximately ten times higher for H in the O-site (Table III). Therefore, storing one H atom in the O-site costs about 0.2 eV to deform the surrounding cells if compared with absorption in the T-site. This number agrees well with the value previously obtained from the ab-initio simulation, \( \approx 0.1 \) eV for a fully relaxed lattice, justifying the interpretation derived from these calculations. This approach shows that the main difference between
absorption in the T and O sites is related to the relaxation of elastic energy in neighbouring cells. Only if all the cells are deformed in the same way, i.e. when the system does not need to invest energy again the elastic properties of the surrounding cells, the O-site may become the preferred one.

CONCLUSIONS

For the case of high concentrations of interstitial H in BCC-iron, a large BCT distortion is found favourable with H absorbing preferentially in the octahedral site. This distortion is only possible if the hydrogen concentration is high enough to transform a significant number of unit cells from BCC to BCT. This transformation might form a precursor to the BCC to FCC phase transformation. For the case of low concentration of interstitial H, the energetic cost of deforming the surrounding iron matrix makes preferable absorption in the T-site. Hydrogen diffuses faster around regions of high concentration, where the transition state is located between the T and O sites. In low concentration regions, diffusion takes place between T sites, avoiding the O-site (a local maximum). H absorbed in O or T create a completely different distribution of stresses in neighbouring cells explaining the preference of H for the T-site for cases or regions of low concentration of interstitials.

ACKNOWLEDGMENTS

This work has been financed by the Spanish CICYT (MAT2003-3912 and MAT-2005-3866), and MEC (CONSOLIDERS SEDUREC and NANOSELECT). We are grateful with Dr. R. Ramirez for useful conversations.

FIG. 5: Finite elements simulation of stresses around the fully relaxed $1 \times 1 \times 1$ unit cell upon absorption of H on the O-site (circles, $\circ$, and up-triangles, $\triangle$, in the x and y direction; times, $\times$, in the z one), and T-site (squares, $\square$, and down-triangles, $\triangledown$, in the x and y direction; plus, $+$, in the z one).
