We study families of fermionic field states in noninertial frames which show no entanglement survival in the infinite acceleration limit. We generalize some recent results where some particular examples of such states were found. We analyze the abundance and characteristics of the states showing this behavior and discuss its relation with the statistics of the field. We also consider the phenomenon beyond the single-mode approximation.

I. INTRODUCTION

One of the aims of the novel field of relativistic quantum information is to study the correlations present between field modes as seen by both inertial and accelerated observers. In this context, there have appeared a number of works studying fermionic fields in noninertial frames [1–11]. One of the most well-known scenarios consists in the analysis of the quantum correlations shared between an inertial mode of a fermionic field and an accelerated one, as a function of the latter’s acceleration. Most of the previous literature was centered only in the analysis of pure states from the inertial perspective, where some entanglement was always found to survive in the infinite acceleration limit (see previous citations). This contrasts with the case of bosonic fields, where no field entanglement has ever been found to survive at the infinite acceleration limit, and where it is possible even to completely cancel entanglement at any finite acceleration [10,12,13].

This survival of fermionic entanglement at finite acceleration has been usually linked to the Pauli exclusion principle, which would arguably maintain some entanglement of a statistical nature at any value of the acceleration [4,14]. This has led to some works showing that, for some field states, the entanglement at infinite acceleration is not usable for quantum information [15].

Nevertheless, in some recent works, fermionic entanglement behavior for a family of Werner states has been studied [16], finding fermionic entanglement extinction at finite acceleration for some states of this 1-parametric family. On the other hand, some other works [17] found that if we consider a fermionic tripartite field \( W \)-state shared by two accelerated observers, \( R_1 \) and \( R_2 \), and one inertial, \( A \), i.e.,

\[
|W\rangle = \frac{1}{\sqrt{3}}(|100\rangle + |010\rangle + |001\rangle),
\]

and then we trace out the inertial observer (which is equivalent to considering a system composed of two accelerated partners), then the resulting density matrix

\[
\rho = \frac{1}{3}(|10\rangle\langle 10| + |10\rangle\langle 01| + |01\rangle\langle 10|
+ |01\rangle\langle 01| + |00\rangle\langle 00|)
\]

is entangled at zero acceleration, but shows no entanglement survival for sufficiently high accelerations of the observers. These particular cases show that the phenomenon of fermionic entanglement survival does not happen for any entangled state.

II. SETTING

We consider two noninertial observers in two causally disconnected patches of Minkowski space-time. These observers move with uniform proper accelerations, which are not necessarily equal. In other words, they travel along lines of constant spacelike Rindler coordinate. We will call the observers Rob or Rodney if they are in region I, and anti-Rob or anti-Rodney if they are in region II, as depicted in Fig. 1. Note that although we will refer to the observers by different names depending on the space-time wedge on which they are at, we will always consider only two observers at a time. Each observer probes a single mode of a Grassmann scalar field [1,10], an anticommuting field with only one degree of freedom. We will analyze entanglement between these modes for different field states associated with different observers' accelerations.

The most natural way to describe the quantum field from the viewpoint of these uniformly accelerated observers is through field quantization in the Rindler basis. This means that, whereas an inertial observer would quantize the field using Minkowski modes (positive frequency solutions to the relevant field equation in Minkowski coordinates) to build up the Fock space, it is more appropriate for our observers to quantize the field using Rindler modes (positive frequency solutions in
Rindler coordinates. This is so because any particle detector carried by the accelerated observers would couple directly to Rindler rather than Minkowski modes. The existence of two causally disconnected regions as depicted in Fig. 1 implies that, for each Rindler frequency, there are two different Rindler modes, each of them having support only in either region I or II. When considering a general field state, both kinds of modes have to be taken into account.

To study entanglement in noninertial frames, it is convenient to use the so-called Unruh modes [10]. The annihilation operators associated with these modes have simple expressions in terms of Rindler creation and annihilation operators for particles \( e^{\omega \cdot c \omega} \) and antiparticles \( d^{\omega \cdot \Pi} \), namely,

\[
\begin{align*}
C^{\dagger}_{\omega, R} &= \cos r_{\omega} C_{\omega, 1} + \sin r_{\omega} d_{\omega, \Pi}, \\
C^{\dagger}_{\omega, L} &= \cos r_{\omega} C_{\omega, 1} - \sin r_{\omega} d_{\omega, \Pi},
\end{align*}
\]

where \( \tan r_{\omega} = e^{-\pi \omega c / a} \) and \( \omega \) indicates the Rindler frequency as measured by a Rindler observer with proper acceleration \( a \). This acceleration is merely a convention which amounts to the choice of a specific Rindler observer in order to label frequencies; alternatively, we could index the modes by their dimensionless Rindler frequency \( \Omega = \omega / a \). The subscripts \( L \) and \( R \) stand for “left” and “right” modes, respectively, which are related to each other by a reversal of regions I and II. These modes have the particularity of being linear combinations of purely positive-frequency Minkowski modes. This implies that the Minkowski and Unruh vacua are the same. Therefore, the Hilbert space factorizes as

\[
|0\rangle_M = \bigotimes_{\omega} |0\rangle_{\omega, U},
\]

where each \( |0\rangle_{\omega, U} \) is annihilated by \( C_{\omega, R} \) and \( C_{\omega, L} \).

Given (4), we only need to study in detail two of the factors in the tensor product, one for each observer, and hence from now on we will consider only the frequencies \( \omega_1 \) for Rob and \( \omega_2 \) for Rodney. The relevant part of the vacuum will be written as

\[
|0\rangle_U = |0\rangle_{\omega_1, U} |0\rangle_{\omega_2, U}.
\]

We will consider arbitrary Unruh excitations of the form [10]

\[
|1\rangle_{\omega_1, U} = C_{\omega_1, U}^\dagger |0\rangle_U = (q_{\omega_1} C_{\omega_1, R} + q_{\omega_1} C_{\omega_1, L}) |0\rangle_U,
\]

where \( |q_{\omega_1}|^2 + |q_{\omega_1}|^2 = 1 \), \( i = 1, 2 \).

The case \( q_{\omega_1} = 1 \) corresponds to the choice previously known as the single-mode approximation [18,19]. Notice that since we have endowed the fermionic Fock space with a particular tensor product structure, one must be careful because the choice of a particular tensor product structure may affect entanglement. We will assume the most extended way of building the fermionic Fock space [10] as it allows us to easily find the relevant expressions for the field states and the main results about entanglement vanishment remain true. For a detailed study of these issues, see [20].

To study field entanglement, we need to express the Minkowski vacuum and the particle excitations in the Rindler basis. This is easily done from Eqs. (3) and (5) once we impose that the vacuum be annihilated by all four relevant Unruh operators \( C_{\omega_1, R}, C_{\omega_2, L}, C_{\omega_2, R}, \) and \( C_{\omega_2, L} \). If, following previous notation [10], we choose a basis for each factor space in (5) by

\[
|i j k l\rangle = (e_{\omega_1, 1}^i)^\dagger (d_{\omega_1, \Pi}^j)^\dagger (e_{\omega_1, 1}^l)^\dagger (d_{\omega_1, \Pi}^r)^\dagger |0\rangle_{\text{Rindler}},
\]

where \( i, j, k, l \in \{0, 1\} \) due to the Pauli exclusion principle, the Unruh vacuum may be expressed in the Rindler basis through (5) with (see [10])

\[
|0\rangle_{\omega_1, U} = \cos^2 r_{\omega_1} |0000\rangle - \sin r_{\omega_1} \cos r_{\omega_1} |0011\rangle + \sin r_{\omega_1} \cos r_{\omega_1} |1100\rangle - \sin^2 r_{\omega_1} |1111\rangle.
\]

The excitations can now be straightforwardly computed using (5), (6), and (8).

Now we have the states necessary to study field entanglement as seen by two accelerated observers.

One last point remains before the discussion of the formalism is complete: As it is obvious from Fig. 1, a uniformly accelerated observer lying in one wedge of space-time is causally disconnected from the other. It is therefore necessary for him to trace out the field modes which are unobservable. Since we have two such observers which can lie in either regions of Rindler space-time, two partial traces need to be taken, resulting in one of the four following situations:

1. Rob–Rodney, in which the region II modes are traced for both the \( \omega_1 \) and \( \omega_2 \) subspaces;
2. Rob–anti-Rodney, in which region II modes are traced for \( \omega_1 \) and region I modes are traced for \( \omega_2 \);
3. anti-Rob–Rodney, in which region I modes are traced for \( \omega_1 \) and region II modes are traced for \( \omega_2 \);
4. anti-Rob–anti-Rodney, in which region I modes are traced for both \( \omega_1 \) and \( \omega_2 \).

In the next section we will study the behavior of entanglement in all these situations, for a general mixed state of

\[
\text{FIG. 1. Minkowski space-time diagram showing the world lines of the noninertial observers under consideration. We always consider only two of them at the same time and label any observer residing in region II with the prefix “anti.”}
\]

\[
\text{042320-2}
\]
the two field modes under consideration. We note that, unlike in previous works \cite{10,21} where field entanglement between an inertial and an accelerated observer was considered, the inertial entanglement is not always recovered in the zero acceleration limit of our setting. Although a naive expectation might be that this should be the case, it is not because of the discontinuity in localization of the Rindler and Minkowski modes: whereas the former are always localized in region I or II of space-time, the latter are supported in the whole of space-time.

III. ENTANGLEMENT SHARED BY TWO ACCELERATED PARTNERS

We consider a general state described by a $4 \times 4$ density matrix $\rho$ written in the basis

\begin{equation}
\mathcal{B} = \{|0\rangle_{\omega_1, U}|0\rangle_{\omega_2, U},|0\rangle_{\omega_1, U}|1\rangle_{\omega_2, U},
|1\rangle_{\omega_1, U}|0\rangle_{\omega_2, U},|1\rangle_{\omega_1, U}|1\rangle_{\omega_2, U}\}. \tag{9}
\end{equation}

This basis of Unruh excitations is to be expressed in terms of the Rindler basis by means of the results of Sec. II. Subsequently, the appropriate partial traces are taken, leaving us with a reduced state $\rho'$ containing all the observable correlations between field modes.

As a distillable entanglement measure valid for mixed states, we employ the negativity \cite{22}. From now on when we refer to the negativity of a bipartition, we mean the negativity of the corresponding $\rho'$ matrix.

We will first study the phenomenon of entanglement extinction with a Monte Carlo method \cite{23} to probe the space of density matrices and find out the abundance of states whose entanglement disappears for finite accelerations.

Then, motivated by the observation that entanglement extinction in the fermionic case appears only for nonpure states, we will obtain a typical distance (in the sense of degree of purity) between maximally entangled states and the first mixed states where the phenomenon appears.

A. Monte Carlo survey

The relevant parameter space ($4 \times 4$ state matrices) is a 15-dimensional manifold $\mathcal{M}$. We relied on a Monte Carlo method to numerically estimate the abundance of states showing some inertial entanglement which vanishes at infinite acceleration of both partners in the Rob-Rodney bipartition. Our algorithm works as follows: First, we randomly generate a $4 \times 4$ matrix $G$ drawn from the Ginibre ensemble \cite{24} (normally distributed matrices with identical variance in both real and imaginary parts of all its entries). Then, a state matrix $\rho$ is obtained as

\begin{equation}
\rho = \frac{G G^\dagger}{\text{Tr}(G G^\dagger)}, \tag{10}
\end{equation}

and we checked whether if it had some inertial entanglement by directly computing the negativity of the matrix $\rho$. If so, entanglement at infinite acceleration of both partners was studied.

The use of a matrix $G$ in the Ginibre ensemble, together with the correspondence (10), induces the Hilbert-Schmidt measure in $\mathcal{M}$ \cite{25}, a measure both unitarily invariant (meaning that any two measurable subsets $A_1$ and $A_2$ related through a unitary $U$ such that $A_2 = U A_1 U^\dagger$ have the same measure) and obtained from a metric. Once we have a measure on $\mathcal{M}$, such questions as “How many states show entanglement survival at infinite acceleration?” become meaningful. Though this unitarily invariant measure is not a unique choice \cite{25,26}, its behavior is well understood under certain circumstances \cite{26} and is simple enough to generate states with it.

To gain some physical insight on the behavior of the induced measure in the space of density matrices, we generated $10^6$ states, plotting a histogram of their inertial negativities, which can be seen in Fig. 2. Approximately 76 % of these states were entangled, distributing themselves over a Gaussian.

We found that from a sample of $10^5$ points, 75.9 % showed nonzero negativity, and that

1) for $q_R = 1$ (the single-mode approximation), 85 % of the states with nonvanishing inertial entanglement had zero entanglement in the limit of infinite acceleration for both observers;

2) for $q_R = 0.97$, 79 % of the states with inertial nonvanishing entanglement had zero entanglement in the limit of infinite acceleration for both observers;

3) for $q_R = 1/\sqrt{2}$, 75 % of the states with nonvanishing inertial entanglement had zero entanglement in the limit of infinite acceleration for both observers.

The results above show that the phenomenon of entanglement extinction at infinite acceleration (and, as we shall see in Subsec. III B, at finite acceleration) is fairly common and not a peculiarity of some specific family of states. Also, the percentage of states showing the phenomenon drops with $q_R$, which is consistent with previous results that going beyond the single-mode approximation could result in entanglement amplification \cite{27}.

B. Some states in detail

In this subsection, some of the states showing the phenomenon of vanishing entanglement at infinite acceleration
are analyzed thoroughly. More specifically, we computed the negativity for all four possible bipartitions for the state (2) which first showed the phenomenon. Considering previous results in [10], it might have been reasonable to guess that entanglement is not destroyed, but rather transferred to the other bipartitions. This would have been expected considering the results obtained for maximally entangled states. We present our results in Fig. 3.

We remark that whenever there is entanglement vanishing at some acceleration in the Rob–Rodney bipartition, the entanglement vanishes in all other bipartitions and for all values of acceleration as well. We have thus established that entanglement is not merely being redistributed among the various possible bipartitions, but rather that it is lost. Although true for pure entangled states, it is not true in general that fermionic statistics directly implies entanglement survival. We have seen that for some nonpure fermionic states, entanglement extinction due to acceleration might happen. However, it is true that entanglement survival in the infinite acceleration limit is only possible if there is some entanglement transfer to other bipartitions, as it was concluded in [21]. Note that the correlations between Rob and anti-Rodney only show up when \( r_{\text{uni}} \) is far from \( r_{\text{uni}} \). In other words, there are only correlations in this bipartition if the accelerations or the field modes they watch are very different.

The region where entanglement is zero for all bipartitions does not include points with \( r_{\text{uni}} = 0 \) or \( r_{\text{uni}} = 0 \). However, for other states, such as the one given by the density matrix \( \rho = \alpha + i\beta \),

\[
\alpha = \begin{bmatrix}
0.0564 & 0.0190 & 0.0515 & 0.1014 \\
0.0190 & 0.1902 & 0.0394 & 0.1575 \\
0.0515 & 0.0394 & 0.2174 & 0.2247 \\
0.1014 & 0.1575 & 0.2247 & 0.5360
\end{bmatrix},
\]

\[
\beta = \begin{bmatrix}
0 & -0.0089 & -0.0645 & -0.0339 \\
0.0089 & 0 & -0.0233 & 0.0149 \\
0.0645 & 0.0233 & 0 & 0.0962 \\
0.0339 & -0.0149 & -0.0962 & 0
\end{bmatrix}, \quad \text{(11)}
\]

The region of vanishing entanglement does indeed include such points. Since in the single-mode approximation the limit of the Unruh modes for zero acceleration yields modes confined to region I, this means that this behavior is also present where there was only one accelerated observer. The only simple requirement is thus to consider mixed states, as pure states do not present this behavior.

As mentioned above, there is some entanglement in the Rob–anti-Rodney bipartition whenever Rob’s acceleration is higher than anti-Rodney’s and these accelerations are not close. The corresponding result but with anti-Rob–Rodney correlations is also true.

We also point out that all the states studied under the single-mode approximation show the same qualitative behavior: Entanglement decreases monotonically along the diagonal up to a threshold value of \( r \) where it hits zero, staying there onwards. Higher values of inertial entanglement correspond to higher values of this threshold. It seems likely that the threshold can achieve all the values of \( r \) if we allow arbitrarily low inertial entanglement, although we have not proved this.

These results are derived assuming the single-mode approximation \( q_R = 1 \). This assumption introduces a strong asymmetry between region I and region II modes, which explains why there are no states showing the same behavior for the anti-Rob–anti-Rodney bipartition. Figure 4 shows the same plot for negativity as a function of acceleration for state (2), when \( q_R = 1/\sqrt{2} \). The behavior is qualitatively different once the single-mode approximation is relaxed; there can be entanglement amplification maxima (see [27]), and the negativity no longer gives rise to a smooth surface. Also, due
to the symmetry between regions present when $q_R = 1/\sqrt{2}$, all four bipartitions result in the same surface.

C. Radius of entanglement survival

This phenomenon of entanglement destruction at infinite acceleration has only been observed for mixed states. Since maximally entangled states are pure, this means that entanglement survival at infinite acceleration should be expected as long as we do not stray “too far” from maximally entangled states. To determine the precise meaning of “too far,” we developed the following scheme: After generating a random state matrix $A$ in the same way as for the Monte Carlo algorithm above, we computed the negativity at $r_{\text{max}} = r_{\text{min}} = \pi/4$ under the single-mode approximation as a function of $p$ for the family of states

$$\rho(p) = (1 - p)|\Psi\rangle \langle \Psi| + pA, \quad p \in [0,1],$$

$$|\Psi\rangle = \frac{1}{\sqrt{2}} (|00\rangle + |11\rangle).$$

until a value of $p$ for which the negativity dropped to zero was found. This defines a function $f: \mathcal{M} \rightarrow \mathbb{R}$ from the space of state matrices to the real numbers. Since $\mathcal{M}$ is compact, it follows that $f$ has a minimum value, which may be regarded as a measure of how far from the maximally entangled state of our choice is the set of states with zero entanglement in the infinite acceleration limit.

The process was repeated for $10^6$ random matrices, using the same generating method as in Subsec. III A. The minimum value of $p$ was found to be $p = 0.29$. This means that for any one-parameter family of states of the form (12), with a high degree of certainty, the states never become mixed enough to wipe out entanglement at infinite acceleration before this value of $p$ is attained. This further confirms that the phenomenon is linked to noncoherent states, since it does not show up near entangled states.
