Abstract: The Lascaux Cave in France is an old karstic channel where the running waters are collected in a pool and pumped to the exterior. It is well-known that water bodies in the vicinity of humans are suspected to be reservoirs of amoebae and associated bacteria. In fact, the free-living amoebae Acanthamoeba astronyxis, Acanthamoeba castellanii, Acanthamoeba sp., and Hartmannella vermiformis were identified in the sediments of the cave using phylogenetic analyses and morphological traits. Lascaux Cave sediments and rock walls are wet due to a relative humidity near saturation and water condensation, and this environment and the presence of abundant bacterial communities constitute an ideal habitat for amoebae. The data suggest the need to carry out a detailed survey on all the cave compartments in order to determine the relationship between amoebae and pathogenic bacteria.

INTRODUCTION

Free-living amoebae (henceforth, amoebae) are ubiquitous and found in a variety of habitats, largely aquatic, but also in soils and sediments. In aquatic environments, the ecological distribution of amoebae encompasses natural and treated water, drinking water treatment plants, swimming pools, sewage, etc. (Khan, 2006). However, amoebae have been scarcely investigated in caves (Coppellotti & Guidolin, 2003; Mulec, 2008; van Hengstum et al., 2009; Walochnik & Mulec, 2009; Mazei et al., 2012). Caves harbour pools, lakes and subterranean rivers, and the sediments and rock walls are constantly wet due to a relative humidity near saturation and water condensation. This environment and the presence of abundant bacterial communities (Bastian et al., 2009; Saiz-Jimenez et al., 2011) constitute an ideal habitat for amoebae.

Lascaux is an uncommon cave which experienced a strong anthropogenic impact. In fact, after opening in 1948, the Lascaux Cave was highly impacted by massive tourism, and suffered several microbial outbreaks, the first one of the Chlorophyta Bracteacoccus minor in 1963 due to the effect of an artificial lighting system (Lefèvre, 1974). Further, fungal outbreaks of Fusarium solani and melanised fungi were evidenced in 2001 (Bastian et al., 2010; Martin-Sanchez et al., 2012). Lascaux Cave is different from all other studied caves because was treated for years with benzalkonium chloride to control the fungal outbreaks.

A climate regulation system was installed inside the cave in 1957, with several replacements, the last one in 2001. Therefore, it was not surprising that Bastian et al. (2009) found in many sediment samples the simultaneous presence of sequences related to Legionella, Apifia, Aquicella, and bacterial endosymbionts of amoebae, common in climate systems. The finding of these bacteria motivated us to carry out a survey on the cave sediments in a search for amoebae.

MATERIAL AND METHODS

Four samples were collected from Lascaux Cave sediments (Fig. 1); on 17 February 2010 from a black stain located in the Apse (M6), on 21 September 2010 from the Painted Gallery (S1 and S2) and on 29 September 2010 from the Chamber of Felines (DF). These sites corresponded to the areas in which...
abundant bacterial endosymbionts were previously detected (Bastian et al., 2009). Cave environmental data were reported elsewhere (Lastennet et al., 2011).

Samples were maintained at 5°C for 48 hours, during the transport to the laboratory. Upon arrival, the samples were incubated and subjected to cloning and axenisation following standard methods (Page, 1967a, b). Samples M6 and S2 showed an intense fungal contamination, which required continual reseeding, in addition to antifungal treatments with 0.5% nystatin.

For taxonomical identification of amoebae standard methods described by Pussard & Pons (1977, 1979) were used. Trophozoites (feeding stage of amoebae) and cysts (surviving stage during adverse environmental periods) were observed in a Zeiss stereomicroscope IVB, and the images captured with an Olympus camera SP-500 UZ.

DNA extraction from the cultures was performed using the FastDNA SPIN Kit for Soil (MP Biomedicals, OH, USA) according to the manufacturer’s instructions. The specific detection of Acanthamoeba spp. was performed by PCR using the primers set JDP1 (5'-GGCCCAGATCGTTTACCGTGAA-3') and JDP2 (5'-TCTCACAAGCTGCTAGGGGAGTCA-3'), which specifically amplify a 450 bp fragment of the 18S rDNA gene in the genus Acanthamoeba (Schroeder et al., 2001). The amplification products were sequenced using the same primers and the obtained sequences were compared with those deposited in GenBank using the NCBI BLASTn algorithm. Phylogenetic relationships between the Acanthamoeba spp. isolated from Lascaux Cave and the closest related sequences from GenBank were conducted using MEGA 5.0 with the Maximum-Likelihood method. Gaps were treated as missing data and bootstrap values were generated using 1000 replicates. The resulting topology was compared with results from other treeing algorithms, including the Neighbor-Joining and Maximum-likelihood methods. The resulting topology was compared with results from other treeing algorithms, including the Neighbor-Joining and Maximum-likelihood methods. The resulting topology was compared with results from other treeing algorithms, including the Neighbor-Joining and Maximum-likelihood methods. The resulting topology was compared with results from other treeing algorithms, including the Neighbor-Joining and Maximum-likelihood methods. The resulting topology was compared with results from other treeing algorithms, including the Neighbor-Joining and Maximum-likelihood methods.

In order to identify other genera of amoebae, a region of 18S rDNA was amplified using the primers set EukA (5'-AACCTGGTTGATCCTGCCAGT-3') and EukB (5'-TGATCTTCTGAGTTACCTAC-3') as described by Diez et al. (2001). Clone library was constructed using this purified PCR product, using standard methods.

RESULTS AND DISCUSSION

Direct microscopy observations allowed the identification of trophozoites and cysts of the genera Acanthamoeba and Hartmannella in sample S1 (Table 1). In sample DF were also present species of the genera Acanthamoeba and Hartmannella, but the species of Acanthamoeba was different to that found in sample S1 (Fig. 2). In sample S2 only a species of Acanthamoeba, similar to that found in sample DF, was observed. However, trophozoites or cysts of Hartmannella, unlike the other two samples, were not detected. In sample M6 only trophozoites of Acanthamoeba but no cysts were detected, therefore its morphology could not be defined.

The genus Acanthamoeba could be easily recognized in sample S1 because of the morphological characteristics of the trophozoites and cysts (Fig. 2A, B). Based on the size and morphological features of cysts the Acanthamoeba was identified as A. astronyxis, characterized by large trophozoites and cysts (18 μm), with smooth ectocyst and stellate endocyst (Page, 1967b; Pussard & Pons, 1977). The 18S gene sequence showed a 99% similarity with the type strain A. astronyxis (ATCC30137), isolated from water, and genotype T7 according to Stothard et al. (1998). In the phylogenetic analysis these two strains also formed a homogenous cluster with 81% of bootstrap value confirming the species identification (Fig. 3).

The Acanthamoeba sp. found in sample DF corresponded to a different species. The strain is close related to A. mauritaniensis because some endocysts had fewer than 6-rays and the cysts showed reticulation even after fixation with formaldehyde in the heat impregnation technique (Fig. 2C) (Pussard & Pons, 1977). However, analysis of the 18S gene sequence from this strain showed a 99% similarity...
Acanthamoeba sp. strain UWET, used by Horn et al. (1999) to describe the genotype T14. In the phylogenetic analysis these two strains form a homogenous cluster with 94% of bootstrap value, clearly separated from A. castellanii (Fig. 3).

In the Acanthamoeba sp. S2 strain, the morphological classification leads to a similar result to that obtained for the sample DF as denotes the similarity in size of the cysts. However, periodic acid thiocarbohydrazide silver reduced staining (PATAg-r) (Pussard & Pons, 1979) shows a somewhat different feature. In this case, the opercular complexes are stained more markedly, showing very characteristic concentric circles (Fig. 2D). Heat impregnation shows clearly the cysts reticulation, similar to that obtained in the sample DF (Fig. 2C, E). In sample M6 only trophozoites of Acanthamoeba sp. were observed, but not the presence of cysts in the culture plates, thus preventing a morphological characterization.

The 18S gene sequences from S2 and M6 strains were identical, confirming that they are the same species. These Acanthamoeba sp. showed a 99% of similarity with different strains of A. castellanii (genotype T4) including the type strain Castellani. In the phylogenetic analysis of 18S gene, and comparison with GenBank by BLAST algorithm (NCBI), similarity percentages are included. Classification according to Stothard et al. (1998).

*Morphological identification based on microscopic studies of trophozoites and cysts.

**Molecular identification based on phylogenetic study of 18S gene, and comparison with GenBank.

**Accession numbers in parentheses. T1, T4, T7, T8, T9, T11 and T14 are recognised Acanthamoeba genotypes. The tree was constructed using the Maximum Likelihood method applying Hasegawa-Kishino-Yano model, based on a comparison of 317 nucleotides. The tree with the highest log likelihood (-739.4) is shown. It was rooted with Procatamnaoeba bohemicus (Acanthamoebida) as outgroup.

Bootstrap values are expressed as percentages of 1,000 replications. All nodes of the tree were also recovered using Neighbour Joining and Maximum Parsimony treeing algorithms. Bar, 0.01 substitutions per nucleotide position.

ATCC 50374 isolated from a yeast culture and the strain Ma ATCC 50370 from a keratitis patient. Also showed 99% of similarity with strains of A. polyphaga, and 96% similarity with A. mauritaniensis, both species included in the genotype T4. This genotype was reported as the one most commonly found in the environment (Booto et al., 2002) and was associated to a high percentage of amoebic keratitis (Stothard et al., 1998). The phylogenetic analysis (Fig. 3) and the morphological traits (Pussard & Pons, 1977) suggested that S2 and M6 strains would be A. castellanii.

Strains of the genus Hartmannella was found in sample S1 and DF. The description of Page (1976) for the genus Hartmannella is coincident with our strains, and they were identified as H. vermiformis (Fig. 2F). Molecular data confirmed the identification of the strain isolated from sample S1 (Table 1). Acanthamoeba castellanii genotype T4, and H. vermiformis were previously found in Slovenian caves (Mulec, 2008; Walochnik & Mulec, 2009).

To understand the presence of amoebae it must be taken into account that the Lascaux Cave is an old karstic channel with many water percolation points and a main emergence point at the entrance air-lock. The running waters are collected in a pool under the machinery room (a thermic and hygrometric regulation system is installed inside, near the cave entrance) and pumped to the exterior (Lastennet et al., 2011). It is well-known that water bodies in the vicinity of humans are a reservoir of amoebae and associated bacteria (Atlas, 1999).

In a previous paper (Bastian et al., 2009), 696 bacterial clones were retrieved from different Lascaux Cave halls and galleries. Phylogenotypes related with pathogenic bacteria amounted to 45%, from which the presence of Afipia spp., Aquicella spp. and Legionella spp. were remarkable. In addition, other bacteria identified in the cave, such as Achromobacter xylosidans, Stenotrophomonas maltophilia and Pseudomonas fluorescens were reported to be responsible for complete lysis of amoebae or found as intracellular pathogens (Pagnier et al., 2008). Hence, the simultaneous presence of sequences of Afipia, Aquicella and Legionella in some cave halls, and the identification of Acanthamoeba spp. and H. vermiformis suggest a close relationship among intracellular pathogenic bacteria and amoeba in the cave.

Many protozoan species have been found to harbour intracellular Legionella spp. These include H. vermiformis and among other Acanthamoeba, A. castellanii. For some authors it was clear that A. castellanii provided an intracellular niche in which environmental strains of Legionella can proliferate. In addition, growth of Legionella pneumophila in potable water occurs only in the presence of amoebae and L. pneumophila may remain culturable for up to 6 months in a medium containing A. castellanii, whereas free-living Legionella within biofilms may be inactivated within a few weeks (Lau & Ashbolt, 2009).

Srikanth & Berk (1994) reported that amoebae from cooling tower, containing Legionella, may adapt to biocides and may even be stimulated by them. The...
biocides tested by these authors included quaternary ammonium compounds (QAC) and isothiazoline derivatives. In Lascaux Cave benzenalkonium chloride was in use from 2001 till 2004 and isothiazolines were employed in 2008 (Bastian et al., 2010), therefore it is not surprising that amoebae living in the cave were not killed, taking into account their adaptation, the formation of resistant cysts and the relative rapid inactivation of these biocides by biotic and abiotic processes. Berk et al. (1998) reported that QAC and isothiazolines biocides were found useless for eliminating Legionella because these bacteria within Acanthamoeba vesicles were viable after biocide exposure.

The known resistance of encysted amoebae and the endosymbionts to disinfection and biocides (Srikanth & Berk, 1994; Berk et al., 1998), which were tested and applied in Lascaux between 2001 and 2008, and the limited field of action in a cave with rock art result in a pessimistic scenario regarding elimination of these microorganisms. This study also suggests the need to control show caves with massive visits from a sanitary point of view, particularly those with small lakes, artificial pools constructed for aesthetical reasons or with water flows accessible to visitors.

The contamination of Lascaux Cave was a consequence of the increasing number of visitors in the early years, which required a climate regulation system. The subsequent fungal outbreaks were treated with biocides, which profoundly altered the microbial ecosystem of the cave. It was intended that the climate system installed in the year 1957 could mitigate visitor’s ravages by controlling carbon dioxide, wall condensation and relative humidity. Unfortunately, with the perspective of time, the decision adopted was wrong and likely resulted in the origin of the problems that the cave has suffered in its history. Instead, the adoption of a protocol of preventive conservation with adequate control and regulation of visits would have been more advantageous and less harmful to the cave.

ACKNOWLEDGEMENTS

The research was initially supported by the Ministry of Culture and Communication, France, project “Écologie microbienne de la grotte de Lascaux”. Later, the work was supported by the Spanish Ministry of Science and Innovation, project TCP CSD2007-00058. The collaboration of Lascaux staff is highly appreciated.
