Neuroactive steroids influence peripheral myelination:
a promising opportunity for preventing or treating
age-dependent dysfunctions of peripheral nerves

Abstract

The process of aging deeply influences morphological and functional parameters of peripheral nerves. The observations summarized here indicate that the deterioration of myelin occurring in the peripheral nerves during aging may be explained by the fall of the levels of the major peripheral myelin proteins [e.g., glycoprotein Po (Po) and peripheral myelin protein 22 (PMP22)]. Neuroactive steroids, such as progesterone (PROG), dihydroprogesterone (5α-DH PROG), and tetrahydroprogesterone (3α,5α-TH PROG), are able to stimulate the low expression of these two myelin proteins present in the sciatic nerve of aged male rats. Since Po and PMP22 play an important physiological role in the maintenance of the multilamellar structure of PNS myelin, we have evaluated the effect of PROG and its neuroactive derivatives, 5α-DH PROG and 3α,5α-TH PROG, on the morphological alterations of myelinated fibers in the sciatic nerve of 22–24-month-old male rats. Data obtained clearly indicate that neuroactive steroids are able to reduce aging-associated morphological abnormalities of myelin and aging-associated myelin fiber loss in the sciatic nerve.

1. Introduction

The search for molecules that are able to promote healthy aging and reverse age-dependent alterations of the nervous system represents an important goal for biomedical research. The aim of the present review will be to discuss in particular the changes occurring in the peripheral nervous system (PNS), with a particular focus on myelin of peripheral nerves and on its protein components. Recent results obtained in our and other laboratories indicating that neuroactive steroids stimulate the expression of myelin proteins of PNS and are able to counteract the effects of the process of aging on the myelin compartment of peripheral nerves will be summarized.

2. Effect of aging on peripheral nerves

The aging process induces important morphological and functional changes in peripheral nerves. It is well known that large myelinated fibers undergo atrophy, while myelin sheaths increase in thickness and show various irregularities (Thomas et al., 1980; Dyck et al., 1981; Grover-Johnson and Spencer, 1981; Adinolfi et al., 1991; Johansson et al., 1996). In the sciatic nerve of normal old cats, anomalies are characterized by the retraction of the lateral loops adjacent to the nodes of Ranvier, by vacuolation, by fragmentation or by the appearance of “bubbles”. At the ultrastructural level, different stages of demyelination are evident. In particular, it is possible to observe an accumulation of mitochondria, lipid-like droplets, as well as heterogeneous granular and vacuolar materials in the outer cytoplasmic compartment of Schwann cells, and in the distended portion of the inner adaxonal rim (Adinolfi et al., 1991). Disruption of one or more segments of the myelin sheaths also occurs; this disruption is produced by interlamellar splitting and ballooning along the major dense line and the intraperiod lines (Adinolfi et al., 1991). Peripheral nerves of rats show similar morphological changes (e.g., myelin ballooning, splitting, infolding, reduplication and remyelination) (Knox et al., 1989; Verdu et al., 2000). We have recently observed that in sciatic nerves of both young and aged rats, the density of myelinated fibers was significantly increased in aged animals (659 ± 366 fibers per nerve in young and aged rats, respectively; P < 0.05) (Azcoitia et al., 2003). The effect of aging is particularly evident in myelinated fibers of small caliber. Thus, more than 60% of the myelinated fibers with a diameter under 5 μm are lost in aged animals (2459 ± 182 versus 900 ± 161 fibers per nerve in young and aged rats, respectively; P < 0.05). The total number of unmyelinated axons is also significantly reduced by aging (16,194 ± 1742 versus 11,130 ± 823 axons per nerve in young and aged rats, respectively; P < 0.05) (Azcoitia et al., 2003).

Alterations in the size and shape of myelinated fibers also occur with aging. The majority (>80%) of myelinated fibers in the sciatic nerve of young rats show a circular or ovaloid profile in cross-sections. However, lobulated, triangular and crescent-shaped profiles are also observed (Azcoitia et al., 2003). The irregular shapes are increased with aging. Thus, less than 50% of the myelinated fibers in old animals had a circular or ovaloid profile (17 ± 3% versus 55 ± 3% of fibers with irregular shapes in young and old rats, respectively; P < 0.05) (Azcoitia et al., 2003). It is interesting to note that similar changes have been related to a decrease of neurofilament mRNA levels; as shown by Parhad et al. (1995), such levels decreased at the levels of rat PNS of about 60% at 23 months of age.

Moreover, the aging process also affects functional parameters. For instance, electrophysiologic studies have shown that nerve conduction velocity is lower in aged subjects than in young ones (Verdu et al., 2000). However, the rate of decline of nerve conduction velocity depends on the type of fiber (afferent versus efferent), the nerve and the animal species (Wagman and Lesse, 1952; Norris et al., 1953; Wayner and Emmers, 1958; Burke et al., 1974; Sato et al., 1985; Swallow and Griffiths, 1977; Rivner et al., 2001). For...
instance, in aged rats, there is no change in the conduction velocity of the phrenic nerve until 28 months of age (Smith and Rosenheimer, 1984), but a decrease in spinal nerve is evident (Rettalaff and Fontaine, 1965; Koella, 1979). In female mice, the amplitude of muscle action potentials recorded from the plantar and tail muscles decreases linearly with age from 2 to 24 months. Furthermore, the latency of the onset of the muscle action potential declines from 2 to 6 months, remains unchanged between 6 and 12 months, and is increased in older mice (Verdi et al., 1996). On the contrary, the conduction velocity of unmethylated fibers seems to be unaffected by the aging process (Sato et al., 1985).

4. Neuroactive steroids

In the last decade, several observations have shown that the capability to synthesize steroid hormones is not only a feature of classical steroidogenic tissues (e.g., gonads and adrenals) but may also occur in the nervous system, forming neurosteroids (Baulieu, 1998; Mellon and Griffin, 2002). Moreover, the nervous system is also able to metabolize neurosteroids into metabolites known as neuroactive steroids. Formation of neurosteroids and neuroactive steroids seems to take place mainly in the glial compartment, and in the PNS is particularly located in Schwann cells (Koeng et al., 1995; Melcangi et al., 1992, 1998a, 1999b, 2001a,b). This enzymatic complex formed by both 5α-reductase (5α-R) and 3α-hydroxysteroid dehydrogenase (3α-HSD) (Melcangi et al., 1992, 1998a, 1999b, 2001a,b). This enzymatic complex is present both in peripheral nerves (e.g., sciatic nerve) and in Schwann cells in culture. In particular, the 5α-R activity of Schwann cells is higher than that of oligodendrocytes, their CNS equivalent (Melcangi et al., 1992, 1998a, 1999b, 2001a,b). This enzyme complex is very versatile, since every steroid possessing the delta 4-keto configuration may be first 5α-reduced and subsequently 3α-hydroxylated. In particular, testosterone (T) can be converted into dihydrotestosterone (DHT) and then into 3α-androstan-3α,17β-diol (3α-Diol), PROG into 5α-DH PROG and subsequently into 3α,5α-T H PROG and so on (Melcangi et al., 1999b, 2001b). The 5α-R:3α-HSD enzymatic complex is present both in peripheral nerves (e.g., sciatic nerve) and in Schwann cells in culture. In particular, the 5α-R activity of Schwann cells is higher than that of oligodendrocytes, their CNS equivalent (Melcangi et al., 1998a), and similar to that found in fetal neurons (Melcangi et al., 1999b, 1993, 1994). In contrast, Schwann cells possess lower 3α-HSD activity than oligodendrocytes (Melcangi et al., 1998a). Schwann cells not only possess the capability to form neuroactive steroids but are also a possible target for some of them. As demonstrated by our own and other laboratories, Schwann cells express mRNA for progesterone receptor (PR) and also the protein itself (Jung-Testas et al., 1996; Magnaghi et al., 1999, 2001). Moreover, they also express non-classical steroid receptors, for instance, the GABA A receptor (Melcangi et al., 1999a). Consequently, Schwann cells may respond to neuroactive steroids, such as 3α,5α-T H
5. Aging affects myelin protein levels and neuroactive steroid formation

A clear decrease in the levels of protein Po has been reported in the sciatic nerve of aged rats (Uchida et al., 1986), and in human sural nerve (Koski and Max, 1980). Several observations on the possible effects of aging on peripheral myelin proteins have been made in knockout models (Giese et al., 1992; Martini et al., 1995; Zielasek et al., 1996; Shy et al., 1997; Fruttiger et al., 1995; Nelles et al., 1996; Scherer et al., 1998). For instance, it has been demonstrated that mice lacking one of the two Po alleles by homologous recombination (Po+/−) have the clinical, electrophysiological, and morphological features of acquired demyelinating neuropathies (CIDP). Po+/− mice are clinically normal until 5 months of age, when they begin to develop a “waddling” gait. The gait disorder progresses for the next 6–8 months and then stabilizes. By 1 year of age, these mice develop severe, asymmetric slowing of motor nerves, with temporal dispersion or conduction block. Morphological analysis reveals severe demyelination of motor nerves, with temporal dispersion or conduction block. Post-mortem examination of these mice demonstrated that mice lacking one of the two Po alleles by homologous recombination (Po+/−) have the clinical, electrophysiological, and morphological features of acquired demyelinating neuropathies, such as chronic inflammatory demyelinating polyneuropathy (CIDP). Po+/− mice are clinically normal until 5 months of age, when they begin to develop a “waddling” gait. The gait disorder progresses for the next 6–8 months and then stabilizes. By 1 year of age, these mice develop severe, asymmetric slowing of motor nerves, with temporal dispersion or conduction block. Morphological analysis reveals severe demyelination of motor fibers, focal regions of demyelination and the presence of inflammatory cells. All these pathological changes are even more pronounced at 20 months (Shy et al., 1997). In humans CIDP is evident between 40 and 60 years of age (McCombe et al., 1987; Mendell, 1993).

Our studies performed by in situ hybridization and/or Northern blot analysis have shown that Po, PMP22 and MBP mRNA levels are all significantly decreased in the sciatic nerves of aged male rats (Melcangi et al., 1998a,b, 1999a). Further observations performed by Western blot analysis have indicated that not only mRNA but also the protein levels of Po and PMP22 proteins are decreased during aging (Fig. 1).

These observations agree with, and provide a possible explanation for, the findings quoted in Section 2 of this review, showing that several morphological and functional aspects of peripheral myelin are profoundly modified during senescence (Spencer and Thomas, 1970; Thomas et al., 1980; Grover-Johnson and Spencer, 1981; Johansson et al., 1996; Downie and Newell, 1961; Morales et al., 1987; Adinolfi et al., 1991; Verdú et al., 1996; Melcangi et al., 2000b; Verdú et al., 2000).

The aging process also affects formation of neuroactive steroids in peripheral nerves. We have observed that aging significantly impairs the formation of 5α-reduced metabolites in sciatic nerves of 20-month-old male rats (Melcangi et al., 1990a, 1992). In contrast, aging seems not to affect 3α-HSD activity (Melcangi et al., 1990a, 1992).

Fig. 1. Effect of aging on the expression of Po and PMP22 in the sciatic nerve of male rats (22–24 months old). (A) Representative Western blot of one experiment performed. (B) Quantitative data, expressed as percent variation vs. levels detected in adult (3 months old) male rats (baseline). The columns represent the mean ± S.E.M. of all determinations performed (numbers in parentheses). **P < 0.01 vs. baseline.

6. Effects of neuroactive steroids on peripheral myelin proteins

As mentioned in the previous section, aging is associated with a decrease in the synthesis of Po and PMP22 (Melcangi et al., 1998a,b, 1999a, 2000b). Moreover, as mentioned in Section 4, on the basis of the presence of classical and non-classical steroid receptors, it is now well known that peripheral nerves and in particular its glial component (i.e., Schwann cells) represent a possible target for the actions of neuroactive steroids. Consequently, we have evaluated whether neuroactive steroids could counteract the drop of Po and PMP22 levels found in the sciatic nerve of aged animals (Melcangi et al., 1998a,b, 1999a, 2000b). To this end, we have treated old male rats (22–24 months old) for 1 month with eight subcutaneous injections of 1 mg of PROG, 5α-DH PROG or 3α,5α-T PROG. Injections were administered every 4 days and mRNA levels of Po and PMP22 were evaluated in the sciatic nerve by Northern blot analysis, 24 h after the last treatment. Only 5α-DH PROG was able to significantly increase the mRNA levels of Po. In contrast, PROG and 3α,5α-T PROG were unable to significantly modify the gene expression of Po (Melcangi et al., 1998a, 1999a).

However, the situation was different when the protein levels of Po were analyzed by Western blot. As shown in Fig. 2, not only 5α-DH PROG but also its precursor PROG were able to increase the low protein levels of this myelin protein present in the sciatic nerve of aged rat, suggesting that additional post-transcriptional effects are exerted by these neuroactive steroids on the synthesis of this myelin protein.
Fig. 2. Effect of in vivo treatment with progesterone (PROG), dihydropro- 
gesterone (5α-DH PROG) or tetrahydroprogesterone (3α,5α-TH PROG) 
on Po protein levels in the sciatic nerve of aged male rats (22–24 months 
old). (A) Representative Western blot of one experiment performed. (B) 
Quantitative data expressed as percent vs. the levels detected in aged rats 
treated with vehicle only (C). The columns represent the mean ± S.E.M. 
of all determinations performed (numbers in parentheses). **P < 0.05 vs. 
controls.

A very similar situation is evident for PMP22. In fact, in 
vivo treatments with PROG, 5α-DH PROG or 3α,5α-TH 
PROG were unable to increase the low mRNA levels of this 
myelin protein found in the sciatic nerve of aged male rats 
(Melcangi et al., 1999a). However, 3α,5α-TH PROG was 
able to significantly increase PMP22 protein levels in the 
sciatic nerve of aged rats (Fig. 3). The effects of PROG 
and/or its derivatives on Po and PMP22 are also evident in 
other in vivo and in vitro experimental models. For instance, 
in the case of Po, in vivo treatments with PROG, 5α-DH 
PROG and 3α,5α-TH PROG were all effective in increasing 
Po gene expression in the sciatic nerve of adult male rats; 
in particular 5α-DH PROG was significantly more effective 
than the other two steroids (Melcangi et al., 1999a). In the 
same experimental model, the mRNA levels of PMP22 were 
significantly increased only by the treatment with 3α,5α-TH 
PROG (Melcangi et al., 1999a).

Neuroactive steroids, like PROG and its derivatives, may 
increase gene expression of myelin proteins after peripheral 
nerve injury. For instance, we have analyzed the possible 
effects of PROG and of its 5α- and 3α,5α-reduced metabo-
lites on the gene expression of Po and PMP22 after transec-
tion and entubulation techniques to repair the sciatic nerve 
of adult male rat (Melcangi et al., 2000a). The data obtained 
indicate that after an experimental period of 2 weeks, both 
PROG and 5α-DH PROG are able to significantly increase 
the low Po mRNA levels present in the distal portion from the 
cut of the sciatic nerve (Melcangi et al., 2000a). These find-
ings are in agreement with the results obtained on the basal 
levels of Po present in the intact sciatic nerve of adult ani-
imals (Melcangi et al., 1999a). However, at variance to what 
was observed in the intact sciatic nerve, 3α,5α-TH PROG 
was ineffective in stimulating Po mRNA levels in this exper-
imental model (Melcangi et al., 2000a). Moreover, 3α,5α-TH 
PROG did not alter PMP22 mRNA levels (Melcangi et al., 
2000a), suggesting that the mechanisms by which this neu-
roactive steroid exerts its effect on the gene expression of 
these myelin proteins might be altered after peripheral nerve 
injury. Beneficial effects of PROG and pregnenolone have 
been also demonstrated by Koenig et al. (1995) who showed 
that both steroids, when given locally, are able to counteract 
the decrease of the amounts of myelin membranes induced 
by a cryolesion in the sciatic nerve of the mouse.

Further experiments performed in our laboratory have 
indicated that the effects of PROG, 5α-DH PROG and 
3α,5α-TH PROG on Po and/or PMP22 gene expression are 
also evident when cultures of rat Schwann cells are used.
In agreement with the in vivo results on the intact sciatic nerve of adult male rats, PROG, 5a-DH PROG and 3a,5a-T PROG in the case of Po, and 3a,5a-T PROG in the case of PMP22, exert a stimulatory effect on gene expression of these myelin proteins (Melcangi et al., 1998a, 1999a). Moreover, as shown by Désarnaud et al. (1998), PROG also stimulates Po gene expression in a different experimental model (Schwann cells transiently transfected with a reporter construct in which the luciferase expression is controlled by the promoter region of the Po gene). However, at variance with our observations, these authors have found that PROG is also able to stimulate the gene expression of PMP22. In this connection, it is also relevant that in Schwann cells co-cultured with dorsal root ganglia neurons PROG is able to accelerate the time of initiation, and to enhance the rate of myelin synthesis (Chan et al., 1998, 2000).

The data so far mentioned clearly indicate that PROG and/or its derivatives, 5a-DH PROG and 3a,5a-T PROG, are able to stimulate the expression of Po and the PMP22. However, they also suggest that the mechanisms involved in these effects are different. Thus, in the case of Po, it is possible that the effects of PROG and 5a-DH PROG might directly involve the PR, which is present both in the sciatic nerve and in cultured Schwann cells (Jung-Testas et al., 1996; Magnaghi et al., 1999, 2001). Moreover, in view of the higher efficacy of 5a-DH PROG, it is also possible to hypothesize that the conversion of PROG into 5a-DH PROG, by 5a-R present in the sciatic nerve and in Schwann cells (Melcangi et al., 1992, 1999b, 2001a,b), is a necessary step. Furthermore, since the activity of the 3a-HSD is bi-directional (Celotti et al., 1992; Melcangi et al., 1999b, 2001b), it is possible to assume that the efficacy of 3a,5a-T PROG, which is not able to directly bind to the PR, may result from a retro-conversion of this steroid into 5a-DH PROG. On the other hand, since 3a,5a-T PROG is a well-known ligand of the GABA<sub>A</sub> receptor (Celotti et al., 1992; Melcangi et al., 1999b, 2001b), also a direct effect of this steroid via the interaction with this neurotransmitter receptor cannot be excluded. As previously mentioned, we have shown that GABA<sub>A</sub> receptor is expressed both in sciatic nerve and in Schwann cell cultures (Melcangi et al., 1999a). The situation is different in the case of PMP22; since only 3a,5a-T PROG is effective, and consequently a possible effect via the GABA<sub>A</sub> receptor might be taken in consideration. Recently, we have investigated these mechanisms using agonists and antagonists of PR and GABA<sub>A</sub> receptor. The data obtained have indicated that, at least in cultures of rat Schwann cells, Po is under the control of PR, while PMP22 depends on the GABA<sub>A</sub> receptor (Magnaghi et al., 2001). An effect on Po through the PR might be also supported by the identification of some progesterone-responsive elements (PRE) on the Po promoter (Magnaghi et al., 1999).

The finding that PROG and/or its derivatives are able to influence the expression of Po and PMP22 in the sciatic nerve of aged rats seems to be a peculiarity of these neuroactive steroids. In fact, T and its derivatives, DHT and 3a-diol, are totally unable to modify the synthesis of these two myelin proteins (Melcangi et al., 2000b). However, the situation is different when other in vivo (adult male rats) or in vitro (rat Schwann cells) experimental models are considered. For instance, in adult male rats, castration clearly decreases the Po mRNA levels in the sciatic nerve by about 40%, and systemic administration of DHT is able to increase the levels of the messenger of this myelin protein (Magnaghi et al., 1999). Since, at variance to what happens with PR, Schwann cells seem not to express androgen receptor (AR) (Magnaghi et al., 1999), we have hypothesized that in our in vivo experiments, the gene expression of Po is stimulated by androgen-dependent mechanisms acting on Schwann cells in an indirect fashion. For instance, androgens might act through the neuronal component, which contains AR (Magnaghi et al., 1999; Jordan et al., 2002). However, with similar treatments in cultures of rat Schwann cells, we have observed that DHT is able to increase the Po mRNA levels (Magnaghi et al., 1999). Consequently, we have tested the hypothesis that DHT might be able to activate Po gene expression by acting through a steroid receptor other than the AR. Since, as mentioned above, 5a-DH PROG, a steroid that interacts with the PR, may activate Po gene expression (Melcangi et al., 1998a, 1999a), we have postulated that DHT might interact with the PR, and activate PRE. The data so far obtained indicate that, in a human neuroblastoma cell line (SK-N-MC) co-transfected with the hPR<sub>B</sub> and with a reporter plasmid containing a PRE, DHT is able to exert a transcriptional activity via the human PR (Magnaghi et al., 1999). Therefore, in addition to a neuronal mediated effect on Po gene expression, a co-operation between progestagens and androgens might be hypothesized.

Moreover, not only the gene expression of Po but also that of PMP22 seems to be modulated by T derivatives. We have observed that, in cultures of rat Schwann cells, 3a-diol is able to significantly increase PMP22 mRNA levels (Magnaghi et al., 2001). This observation is interesting because of its similarity with the efficacy of 3a,5a-T PROG on the same protein (Melcangi et al., 1999a). It has been proposed that 3a-diol, which does not bind to the AR, might interact with GABA<sub>A</sub> receptor (Gee et al., 1988; Frye et al., 1996). Consequently, these observations further support the concept that the PMP22 mRNA levels are stimulated in Schwann cells via the GABA<sub>A</sub> receptor.

7. Effects of neuroactive steroids on morphology of peripheral myelin

On the basis of the effects exerted by neuroactive steroids on Po and PMP22 expression, we have evaluated whether pharmacological treatments with neuroactive steroids may prevent or counteract aging-associated morphological alterations of peripheral nerves. To this purpose, using the same in vivo experimental protocol mentioned in the previous section, we have analyzed the possible effect of PROG,
Fig. 4. Representative photomicrographs from the sciatic nerves of an adult rat (a) and of aged rats (22–24 months old) treated with vehicle only (b), progesterone (c), testosterone (d), dihydroprogesterone (e), dihydrotestosterone (f), tetrahydroprogesterone (g) or 3α-diol (h). All figures are at the same magnification. Scale bar, 25 μm.
5α-DH PROG and 3α,5α-T TH PROG on different morphological parameters of the myelin compartment of sciatic nerve of 22-24-month-old male rats. In a parallel experiment, the possible effects of T and its derivatives, DHT and 3α-diol, have been also analyzed. Data obtained by treatment with PROG, 5α-DH PROG or 3α,5α-T TH PROG indicate that these neuroactive steroids have clear effects on the number and shape of myelinated fibers as well as on the frequency of myelin abnormalities (Azcoitia et al., 2003). In particular, one of the most striking effects of PROG, 5α-DH PROG and 3α,5α-T TH PROG is on myelinated fibers of small caliber (<5 μm) with a significant increase in their number (Fig. 4). In contrast, the number of myelinated fibers of a size larger than 5 μm is not significantly affected by the treatment with these neuroactive steroids. The increase in the number of small myelinated fibers after neuroactive steroid treatment is accompanied by a decrease of similar magnitude in the number of unmeylinated axons and, in particular, to large (>35 μm) unmeylinated axons. Thus, sciatic nerves from rats treated with PROG or its derivatives show a significant decrease in the number of large unmeylinated axons compared to animals treated with vehicle (1746 ± 119, 450 ± 65, 675 ± 46 and 560 ± 66 axons in rats treated with vehicle, PROG, 5α-DH PROG and 3α,5α-T TH PROG, respectively; P < 0.05). Furthermore, the g ratio of small myelinated fibers is significantly increased by PROG or its derivatives. This suggests that the increase in the number of myelinated fibers reflects an increased remyelination of small fibers in aged sciatic nerves.

Another marked effect of the treatments with PROG, 5α-DH PROG and 3α,5α-T TH PROG is the reduction in the frequency of axons with myelin abnormalities. This effect is mainly due to a reduction in the frequency of axons with myelin infoldings, which decreases from 34.6 ± 2.8% of the axons in animals treated with vehicle to 12.1 ± 1.4, 12.1 ± 1.1 and 20.9 ± 2.8% in PROG-, 5α-DH PROG- and 3α,5α-T TH PROG-treated animals, respectively. Moreover, PROG reduces the proportion of fibers with irregular shapes. As mentioned before, myelin abnormalities and irregular fiber profiles are typical markers of the aging process in the sciatic nerve of 22–24-month-old male rats. In a parallel experiment, the possible effects of T and its derivatives, DHT and 3α-diol, on the number and shape of myelinated fibers have been also analyzed. Data obtained by treatment with PROG, 5α-DH PROG or 3α,5α-T TH PROG indicate that these neuroactive steroids have clear effects on the number and shape of myelinated fibers as well as on the frequency of myelin abnormalities (Azcoitia et al., 2003). In particular, one of the most striking effects of PROG, 5α-DH PROG and 3α,5α-T TH PROG is on myelinated fibers of small caliber (<5 μm) with a significant increase in their number (Fig. 4). In contrast, the number of myelinated fibers of a size larger than 5 μm is not significantly affected by the treatment with these neuroactive steroids. The increase in the number of small myelinated fibers after neuroactive steroid treatment is accompanied by a decrease of similar magnitude in the number of unmeylinated axons and, in particular, to large (>35 μm) unmeylinated axons. Thus, sciatic nerves from rats treated with PROG or its derivatives show a significant decrease in the number of large unmeylinated axons compared to animals treated with vehicle (1746 ± 119, 450 ± 65, 675 ± 46 and 560 ± 66 axons in rats treated with vehicle, PROG, 5α-DH PROG and 3α,5α-T TH PROG, respectively; P < 0.05). Furthermore, the g ratio of small myelinated fibers is significantly increased by PROG or its derivatives. This suggests that the increase in the number of myelinated fibers reflects an increased remyelination of small fibers in aged sciatic nerves.

8. Conclusions

The data summarized in the present review indicate that morphological and biochemical parameters of the myelin compartment of peripheral nerve are deeply influenced by the aging process. Interestingly, aging-associated alterations may be counteracted by the treatment with particular neuroactive steroids. Thus, neuroactive steroids are promising agents to prevent age-associated disorders of peripheral nerves. This new concept, when verified in other experimental models, might be extended to pathological situations such as demyelinating diseases (e.g., CMT1A, CMT1B, HNPP, DSS), peripheral nerve injury or diabetic neuropathy. Neuroactive steroids may thus represent useful therapeutic approaches to maintain peripheral nerve integrity.
