Abstract

AIM: The pathogenesis of hypogonadism in liver cirrhosis is not well understood. Previous results from our laboratory showed that IGF-1 deficiency might play a pathogenetic role in hypogonadism of cirrhosis. The administration of IGF-1 for a short period of time reverted the testicular atrophy associated with advanced experimental cirrhosis. The aim of this study was to establish the historical progression of the described alterations in the testes, explore testicular morphology, histopathology, cellular proliferation, integrity of testicular barrier and hypophyso-gonadal axis in rats with no ascitic cirrhosis.

METHODS: Male Wistar rats with histologically-proven cirrhosis induced with carbon tetrachloride (CCL₄) for 11 wk, were allocated into two groups (n = 12, each) to receive recombinant IGF-1 (2 µg/100 g·d·sc) for two weeks or vehicle. Healthy rats receiving vehicle were used as control group (n = 12).

RESULTS: Compared to controls, rats with compensated cirrhosis showed a normal testicular size and weight and very few histopathological testicular abnormalities. However, these animals showed a significant diminution of cellular proliferation and a reduction of testicular transferrin expression. In addition, pituitary-gonadal axis was altered, with significant higher levels of FSH (P<0.001 vs controls) and increased levels of LH in untreated cirrhotic animals. Interestingly, IGF-1 treatment normalized testicular transferrin expression and cellular proliferation and reduced serum levels of LH (P = ns vs controls, and P<0.01 vs untreated cirrhotic group).

CONCLUSION: The testicular barrier is altered from an early stage of cirrhosis, shown by a reduction of transferrin expression in Sertoli cells, a diminished cellular proliferation and an altered gonadal axis. The treatment with IGF-1 could be also useful in this initial stage of testicular disorder associated with compensated cirrhosis.

INTRODUCTION

Hypogonadism (characterized by low testosterone levels and relative hyperestrogenism, loss of libido, sexual impotence and feminine body features in men) is a common complication of advanced liver cirrhosis[1]. Previous data demonstrated that rats with advanced cirrhosis showed reduced testicular size and weight and severe histopathological testicular abnormalities, including reduced tubular diameters, loss of the germinal line, and diminutions in cellular proliferation and spermatogenesis and testicular transferrin expression, a good marker of the integrity of blood-testis barrier[2]. In addition, low serum testosterone and high serum LH were present in cirrhotic animals, as well as decreased levels of serum IGF-1. Interestingly, the administration of IGF-1 at low doses for a short period of time reverted the testicular atrophy and improved the altered pituitary-testicular axis in these animals[3]. In cirrhotic patients, hypogonadism has been attributed to a variety of mechanisms including gonadal toxicities of alcohol, malnutrition and increased production of estrogens from androgens in peripheral tissues due to the existence of portal systemic shunting[4-9].

Insulin-like growth factor-1 (IGF-1) is an anabolic hormone produced in different tissues although the liver accounts for 90% of the circulating hormone, which is synthesized in response to growth hormone (GH) stimulation[10,11]. In cirrhosis the reduction of receptors for GH in hepatocytes and the diminished synthesizing ability of the liver parenchyma caused a progressive fall of serum IGF-1 levels[11-14]. Although in an early stage of cirrhosis serum levels of IGF-1 were normal, its bio-availability seemed to be diminished[15]. The clinical impact of the reduced production or availability of IGF-1 in cirrhosis was largely unknown[11-14]. Recent studies from our laboratory have demonstrated that short courses of treatment with low doses of IGF-1 were able to induce marked improvements in nutritional state[15], nitrogen retention[16], intestinal absorption[17,19], osteopenia[20,21], liver function reducing fibrogenesis[22,23], and restore the reduced somatostatinergic tone[24] in rats with experimental cirrhosis. These data suggest that IGF-1 deficiency plays a pathogenetic role in several systemic complications occurring in cirrhosis.

It is well known that IGF-1 stimulates testosterone synthesis and spermatogenesis[25-32]. Its deficiency could contribute to the development of hypogonadism associated with cirrhosis as...
the previous data supported\cite{2}. Since the pathogenesis of hypogonadism in cirrhosis is not yet well understood, the aim of the present study was to study the chronological progression of the described alterations in testes\cite{3} in advanced cirrhosis, explore testicular morphology, histopathology, cellular proliferation, integrity of testicular barrier and hypophyso-gonadal axis in rats with cirrhosis in an early stage, without ascites.

**MATERIALS AND METHODS**

**Induction of liver cirrhosis**

All experimental procedures were performed in conformity with The Guiding Principles for Research Involving Animals\cite{33}. Cirrhosis was induced as previously described\cite{15,16}. Briefly, male Wistar rats (3-week-old, 130-150 g) were subjected to CCl4 inhalation (Merck, Darmstadt, Germany) twice a week for 11 wk with a progressively increasing exposure time from 1 to 5 min. During the whole period of cirrhosis induction animals received Phenobarbital (Luminal, Bayer, Leverkusen, Germany) in the drinking water (400 mg/L). Both food (standard semipurified diet for rodents; B.K. Universal, Sant Vicent del Horts, Spain) and water were given *ad libitum*. Healthy, age and sex-matched control rats were maintained under the same conditions but receiving neither CCl4 nor Phenobarbital.

**Study design**

The treatment was administrated for 2 wk after stopping of CCl4 exposure. In the morning of d 0, animals were weighed and blood samples were drawn from the retroocular venous plexus from all rats with capillary tubes (Marienfeld, Germany) and stored at -20 °C until for analytical purposes. Cirrhotic rats were randomly assigned to receive either vehicle (saline) (group CI, n = 12) or recombinant human IGF-1 (Pharmacia-Uppsala, Sweden) (2 µg/100 g d in two divided doses, subcutaneously) (group CH+IGF, n = 12) for two weeks. Control rats (group CO, n = 10) received saline during the same period.

In the morning of the 15th d, rats were weighed, blood was obtained from the retroocular plexus and animals were killed by decapitation. After the abdominal cavity was opened, the liver and testes were dissected and weighed. Samples from the left major liver lobe and testes were processed for histological examination (fixed in Bouin’s solution). The testicular diameters (AP and LM) were measured using a precision calliper, Mituyoto® (±0.05 mm). Ascites was ruled out by direct exploration of abdominal cavity in all cirrhotic animals.

**Liver histopathology**

Bouin-fixed tissues were processed and sections (4-µm) were stained with Haematoxylin and Eosin and Masson’s trichrome. Liver histopathology was assessed at 150× magnification. The testicular diameters (AP and LM) were measured using a precision calliper, Mituyoto® (±0.05 mm). Ascites was ruled out by direct exploration of abdominal cavity in all cirrhotic animals.

**Testicular histopathology and PCNA and transferrin immunohistochemistry**

For histopathological evaluation of testes, 30 seminiferous tubules from each rat of the three groups were blindly evaluated by two observers and the arithmetic mean of the scores was taken as the final result. Transverse sections of seminiferous tubuli were examined and evaluation of histological changes was made using a light projection microscope (Micro Promar Leitz GMBH, Wetzlar, Germany) at 150× magnification. The following parameters were studied: tubular diameter, quantification of the presence of different types of cells in tubuli, presence of peritubular fibrosis, and the number of proliferating cells. For general purposes haematoxylin & eosin stain and Masson’s trichrome stain were used. Specific techniques for other purposes are specified in the corresponding paragraphs.

Changes in tubuli were classified into 5 categories (Category I: highest damage to Category V: full normality). Category I: presence of only Sertoli cells; category II: Sertoli cells plus spermatids; category III: Sertoli cells, plus spermatides, and spermatocytes; category IV: presence of all kinds of cells but showing some morphological alterations (i.e.: severe vacuolization, aberrant cells); category V: presence of all kinds of cells without morphological alterations. The presence of peritubular fibrosis was evaluated in Masson’s trichrome preparations according to the thickness of the staining of collagen deposition surrounding tubuli. Proliferating cells were identified by immunostaining of proliferating cellular nuclear antigen (PCNA) using an avidin-biotin peroxidase method\cite{34} with retrieval of antigen by means of microwave irradiation. Specific anti-PCNA antibody (mouse anti-PCNA, clone PC 10, DAKO, Denmark) biotinylated rabbit anti-mouse IgG (DAKO, Denmark) and the avidin-biotin complex technique (ABC, DAKO kit) was performed. The bound antibodies were visualized by means of 3,3’-diaminobenzidine tetrahydrochloride (Sigma Chemical Company, St. Louis, MO) with nickel enhancement\cite{36}. Finally, samples were slightly counterstained (10 s) in hematoxylin, dehydrated, and mounted in DPX. Controls were performed by substitution of the primary antibody by TBS. The number of PCNA positive cells was recorded. The result was expressed as stained cells per tubuli (arithmetic mean of 30 screened tubuli).

In addition, the expression of transferrin\cite{35} in tubuli was evaluated by immunostaining using similar technique as for PCNA with specific anti-transferrin antibody (obtained from rabbit, RARa/TRF, Nordic Immunological Laboratories, Teknovas, The Netherlands). Transferrin expression was scored from 0 to 4 points. If 30 tubuli expressed transferrin normally all over the germinal epithelium, it was scored 0 points. The remaining scores were obtained according to the following formula: (30-tubuli showing expression of transferrin all over the germinal epithelium)×0.075.

**Analytical methods**

Serum levels of albumin, total proteins, glucose, cholesterol, bilirubin, alkaline phosphatase, transferrin and aminotransferases (AST and ALT) were determined by routine laboratory methods using a Hitachi 747 autoanalyzer (Boehrhringer-Mannheim, Germany). Serum levels of the different hormones were assessed by RIA in a GammaChen 9612 Plus (Serono Diagnostics, Roma, Italy) using specific commercial assay systems: total and free testosterone and estradiol-6, Coat-a-Count, DPC (Diagnostic Products Corporation, Los Angeles, CA); rat luteinizing hormone (rLH) and rat follicle stimulating hormone (rFSH) from Amersham International Plc (Little Chalfont Buckinghamshire, England HP7 9NA); IGF-1 by extraction (Nichols Institute Diagnostics, San Juan Capistrano, USA).

**Lipid peroxidation assessment of testicular homogenates**

Malondyaldehyde (MDA) was assessed after heating samples at 45 °C for 60 min in acid medium. It was quantitated by a colorimetric assay using LPO-586 (Bioxytech; OXIS International Inc., Portland, OR, USA), which after reacting with MDA, generated a stable chromophore that could be measured at 586 nm (Hitachi U 2000 Spectro; Roche).

**Statistical analysis**

Data are expressed as mean±SE. To assess the homogeneity between the three groups of rats a Kruskall-Wallis test was
used, followed by multiple post-hoc comparisons using Mann-
Whitney U tests (two tailed) with Bonferroni adjustment. A
regression model was fitted considering histopathological score.
PCNA or transferrin expression scores and IGF-1 plasma
concentration as the dependent and independent variables
respectively. Within group differences between pre-and post-
treatment values were assessed by means of Wilcoxon matched
pairs signed rank sum test. Any P value less than 0.05 was
considered to be statistically significant. Calculations were
performed by SPSS Win v.6.0. program.

RESULTS
At baseline, CI groups showed abnormal values compared to
controls (CO) in serum levels of alanine aminotransferase
(CO = 26±2; CI = 273±49 IU/L, P<0.01), aspartate aminotransferase
(CO = 55±5; CI = 297±49 IU/L, P<0.001), cholesterol (CO = 82±4;
CI = 115±5 mg/dL, P<0.05), alkaline phosphatase (CO = 310±43;
CI = 701±146 IU/L, P<0.05), bilirubin(CO = 0.4±0.0, CI=1.2±0.3 mg/dL,
P<0.05), total proteins (CO = 6.9±0.1; CI = 6.4±0.2 g/dL, P<0.05)
and albumin (CO = 3.6±0.1; CI = 3.1±0.2 g/dL, P<0.05). No
differences were found between cirrhotic groups.

At the end of the experimental period, all rats from groups
CI and CI+IGF showed established cirrhosis (mixed micro-
macronodular cirrhosis in liver histopathology) with some signs of
portal hypertension (spleen weight, g. CO = 0.8±0.0; CI = 1.4±0.2,
CI+IGF = 1.4±0.1. P<0.001 both cirrhotic groups vs controls).
Ascites was absent in all of the cirrhotic animals.

Testicular morphology and morphometry
The testicular size and volume were normal in the cirrhotic
groups as compared to controls. Morphometric study showed
reduction in testicular weight (in absolute values but not if it
was corrected by body mass) in untreated cirrhotic group as
compared to controls and CI+IGF group. Findings regarding
longitudinal and transverse testicular diameters were similar to
those in testicular weight. Morphometric data in the three
groups are summarized in Table 1.

Testicular histopathology
Figure 1 shows testicular morphology in the three experimental
groups. Testicular histological section of normal rat (CO)
demonstrated active spermatogenesis in normal-size
seminiferous tubuli with thin basement membranes and minimal
peritubular fibrosis. Leydig cells were scarce, being widely
separated by seminiferous tubuli. No evidence of peritubular
fibrosis and other alterations was found in cirrhotic groups.
Cellular analyses (see Methods) in 30 seminiferous tubuli were
performed in each preparation and summarized in Table 2. No
relevant findings were obtained in this morphologic study.

Testicular cellular proliferation, as evaluated by PCNA[35],
was significantly reduced in CI rats while CI+IGF rats showed
values similar to controls (CO: 66±2, CI: 57±1, CI+IGF: 61±1,
P<0.001 untreated cirrhotic group vs controls and P<0.05
CI+IGF vs controls and CI group). Figure 2 shows PCNA
immunohistochemistry (PCNA+cells) in the three groups.

Testicular transferrin, a marker of the integrity of hemato-
testicular barrier[36-38], was evaluated from 0 to 4 points by
immunohistochemistry in testicular slices (see Methods).
Transferrin expression was decreased in CI rats (3.40±0.03
points, P<0.001 vs CO and CI+IGF groups) as compared to
controls (3.98±0.04 points) and to cirrhotic rats receiving IGF-1
(3.76±0.05 points). Figure 3 shows transferrin expression in the
three experimental groups.

Testicular levels of MDA in order to study the likely direct
damage of CCl1 to testes, MDA levels, an index of lipid
peroxidation[39], were assessed in testicular homogenates. No
differences were found between the three experimental groups
in testicular MDA content (nmol/L/mg protein, CO = 9.1±0.8,
CI = 13.0±3.2, CI+IGF = 8.9±1.6).

Pituitary-gonadal axis
Serum levels of sexual hormones are summarized in Table 3. No
significant differences were found between groups, either in
total and free testosterone, or estradiol, or in the ratio of estradiol/
testosterone. However, a significant increase of FSH (P<0.001
vs controls) and also high levels of LH (P = 0.06 vs controls)
were observed in untreated rats with compensated cirrhosis,
suggesting an altered negative feedback since this early stage
of the cirrhosis. On the other hand, LH concentrations were
moved towards normal values in IGF-1 treated cirrhotic group
(P = ns vs controls, and P<0.01 vs untreated cirrhotic rats).

Serum levels of IGF-1
At the time of animal sacrifice (d 15), no significant differences
between the three groups were found in serum levels of IGF-1
(CO: 1030±67, CI: 1165±58, CI+IGF: 1030±38 ng/mL), similar to
those described previously in early stage of cirrhosis[16-18,24].

DISCUSSION

This study demonstrates that rats with compensated CCl4-induced cirrhosis show some testicular alterations and gonadal dysfunction, from early stages of liver cirrhosis. The main finding of this study is that there is an altered hemato-testicular barrier, probably responsible for the reduction of cellular proliferation, as well as a paradoxical response of pituitary-testicular axis.

The occurrence of testicular atrophy and gonadal dysfunction in advanced cirrhosis is a well known clinical event[1,3-9]. Both testicular histopathological abnormalities and low levels of serum testosterone have been described in patients with...
alcoholic and nonalcoholic cirrhosis several years ago\textsuperscript{3-9}. Previous experimental data\textsuperscript{11} showed that severe testicular atrophy and gonadal insufficiency treated with low doses of IGF-1 recovered to normal in a very short time (21 d). Data regarding experimentally induced cirrhosis are, however, scarce. Our previous data showed a severe testicular damage\textsuperscript{23} as manifested by macroscopic testicular atrophy and a variety of histopathological abnormalities including a reduction in tubular diameters, presence of aberrant cells in tubular lumen, peritubular fibrosis, loss of the germinal line and a marked reduction in cellular proliferation. These alterations resembled those found in necropsy studies in alcoholic cirrhosis\textsuperscript{1} and those reported in experimental models of testicular damage such as chronic testicular ischemia\textsuperscript{35}.

The mechanisms responsible for the described alterations are not fully understood, although the relationship between IGF-1 deficiency and testicular damage in cirrhosis was demonstrated in the mentioned work\textsuperscript{23}. In cirrhotic rats included in the current work, no IGF-1 deficiency was present but there was a reduced availability of this hormone as it has been suggested previously\textsuperscript{16,18,22}. Moreover, we have previously demonstrated that the changes induced by cirrhosis in the serum profile of IGF-1 binding proteins further reduce bio-availability of IGF-1 in cirrhotic rats\textsuperscript{16}. In fact, exogenous administration of IGF-1 was able to reverse several abnormalities (decreased food utility and intestinal absorption of nutrients, and somatostatinergic tone and osteopenia) associated with cirrhosis in animals with normal serum levels of this hormone\textsuperscript{16-20,22,24}.

On the other hand, a direct effect of IGF-1 on testes seemed to be the most important factor to explain previous findings\textsuperscript{23}. This idea is supported by the existence of receptors for IGF-1 in Sertoli cells, germ cells and Leydig cells\textsuperscript{25-27} and by findings demonstrating a direct effect of IGF-1 on testes\textsuperscript{27-31}. Since IGF-1 is a well recognized trophic factor for testis, its deficiency could be a contributing factor to testicular damage in cirrhosis.

The present work was designed in order to gain more insights into the mechanisms involved in the pathogenesis of hypogonadism associated with liver cirrhosis. In fact, many factors that have been involved in this process, such as portal systemic shunting\textsuperscript{19,39,40} or undernutrition\textsuperscript{41} were minimized in this early stage of the liver disease. Specifically, this study was targeted to establish the historical progression of the described testicular alterations\textsuperscript{35}.

The blood-testis barrier is considered nearly as specific as the blood-brain barrier\textsuperscript{42,43}. Although all cells require iron from serum transferrin produced by hepatocytes, cells that create a blood barrier such as Sertoli cells in the testis and choroid plexus epithelium in the brain also express the transferrin gene to provide iron to cells sequestered within the serum-free environment. Testicular transferrin expression was a good marker of the integrity of the hematotesticular barrier\textsuperscript{44,45}. A major finding of this work was that transferrin expression by Sertoli cells was reduced in untreated cirrhotic rats. The medical bioavailability of IGF-1 could be due to the mechanism of testicular transferrin reduction. IGF-1 treatment increased the expression of this protein in Sertoli cells of cirrhotic rats (Figure 3). This possibility seemed to be plausible since several metabolic functions of Sertoli cells were also influenced by IGF-1\textsuperscript{19,24,45}.

Interestingly, the recovery of transferrin expression in Sertoli cells observed in our study suggested a role for IGF-1 in maintaining the integrity of the hematotesticular barrier\textsuperscript{23,38}.

The first step of the pathogenesis of testicular atrophy occurring in advanced cirrhosis seems to be the decreased expression of transferrin, showing a dysfunction of Sertoli cells and consequently the disruption in blood-testis barrier integrity. Therefore, the observed reduction of cellular proliferation finally affecting spermatogenesis\textsuperscript{24,46} would be its logical consequence.

A question arises as to whether direct toxicity of CCl\textsubscript{4} on testicular tissue could contribute to testicular injury. Alcohol was known to produce oxidative damage and to be able to pass across testicular barrier\textsuperscript{47,48}. This toxic possibility has been reasonably ruled out by the presence of similar levels of MDA, a marker of lipid peroxidation\textsuperscript{39}, in testicular homogenates from the three experimental groups. Certainly, a slight increase of testicular MDA was found in untreated cirrhotic rats, but this did not reach statistical significance.

In the early stage of cirrhosis, testosterone levels were normal. However, both FSH and LH were increased in untreated cirrhotic animals. This abnormal response of the negative feedback could be an initial hormonal reaction of primary hypogonadism. In advanced stages of cirrhosis, we found increased levels of serum LH associated with a significant reduction of total and free serum testosterone defining a picture of primary hypogonadism, thus ruling out hypothalamic-pituitary dysfunction as the responsible mechanism\textsuperscript{2}. Interestingly, LH levels were reduced by IGF-1 treatment in this series with compensated cirrhosis and an incipient gonadal dysfunction. The significant increase of FSH could be related to the observed reduction of cellular proliferation in cirrhotic rats.

Since a close relationship has been reported between IGF-1 and gonadotropins\textsuperscript{49,50}, our findings require further investigation.

In summary, this study shows an altered hematotesticular barrier from an early stage of cirrhosis and suggests that the reduction of IGF-1 bioavailability may play a critical role in the beginning stage of testicular damage and hypogonadism associated with liver cirrhosis. In addition, these results support the conclusion that the exogenous administration of IGF-1 may be useful for the treatment of testicular alterations in cirrhotic patients.

ACKNOWLEDGEMENTS

The authors wish to express their gratitude to Dr. Bruce Scharschmidt, Chiron, for generously granting the rIGF-1 used in this study. We are as well deeply indebted to the “Real Academia de Medicina de Cataluña” (Barcelona) and Mrs.C. Alonso-Borrás and Mr. J. Celaya for financial collaboration.
