I. INTRODUCTION

The effects of lattice deformations on the electronic properties of graphene have been a topic of interest since the very early days due to the observation of ripples in suspended samples.

Later on, the subject acquired a new dimension after the recognition of the extraordinary mechanical properties of the material and the capability of tailoring the samples to exploit the interplay of mechanical and electronic properties.

The success of the description of the influence of elastic deformations on the electronic excitations in terms of "elastic gauge fields" has been extensively used in the proposals of strain engineering in real and synthetic samples.

The interest in the effective low-energy Hamiltonian of deformed graphene has been reactivated recently based on the apparent discrepancy between the lattice description—tight binding (TB) approximation and subsequent continuum limit—and an alternative geometric approach using the formalism of quantum field theory in curved spaces. There have also been recent claims of the emergence of new gauge fields in the standard TB approach originating from the deformation of the lattice vectors.

Given the rapid progress in this field one obvious question is, have we considered all possible effects of strain on the electronic properties of graphene or are we missing some? This is a crucial question, as particular models and approximations tend to capture specific features of the physics and, as a consequence, are likely to miss other aspects. We may answer this question by using group theory techniques to generate all possible interactions respecting the symmetries of the system, and then try to find a model to estimate the values of their couplings.

The idea of constructing effective actions for physical systems based solely on symmetry considerations has a long tradition both in quantum field theory (QFT) and condensed-matter physics, and lies at the hearth of the Landau Fermi-liquid theory of metals. The Dirac description of the low-energy electronic excitations of graphene in the continuum limit is rooted in the symmetries of the underlying honeycomb lattice, as has been known for a long time. The symmetry approach has been applied to the particular problem of strained graphene, for example, in Refs. 18–22. A highly detailed symmetry construction has been used in Ref. 23 to extract the low-energy Hamiltonian affecting the Raman responses in graphene and, more recently, to explore the influence of the flexural modes on the spin-orbit coupling.

While many previous studies have concentrated on uniform strains, important effects such as the emergence of pseudomagnetic fields and the new vector fields responsible for pseudospin precession require the presence of nonuniform strain. Under nonuniform strain, new interaction terms arise which depend not just on the strain components, but also on their derivatives. In this work we apply standard symmetry based methods to construct a low-energy effective Hamiltonian for graphene in the presence of nonuniform elastic deformations. In order to accomplish this, we set up a systematic expansion in derivatives of the strain and use group theory techniques to guarantee that all the symmetry allowed terms up to a given order are included. Next we compute the coefficients of the most relevant terms—those which will affect the experiments—within a generalized tight-binding approximation, which sheds light on the physical origin and significance of the various interactions in the effective Hamiltonian. Those terms which do not involve derivatives of the strain have been already discussed in the literature, but among the new interactions predicted by the symmetry approach there is one that opens a gap and represents the Zeeman coupling between the elastic pseudomagnetic field and pseudospin. We discuss the physical strength of this coupling within the generalized tight-binding model and analyze some physical consequences.

The paper is organized as follows. In Sec. II we outline the properties of the graphene system relevant to our symmetry analysis and set up a systematic expansion in the derivatives of the strain tensor. Section III summarizes the results of the symmetry analysis and contains a description of all the possible terms in the low-energy Hamiltonian for deformed graphene with at most one derivative. The effects of including
higher derivatives are explored in Sec. III B. In Sec. IV we introduce a generalized tight-binding model which is used to compute the coefficients of the low-energy Hamiltonian both for in-plane strains and out-of-plane distortions (Sec. IV A). We also consider the geometric terms due to frame effects (Sec. IV B) and discuss some physical implications of the new gap opening term (Sec. IV C). In Sec. V we summarize our work and consider possible extensions.

II. EFFECTIVE HAMILTONIAN, DERIVATIVE EXPANSION, AND SYMMETRIES

In this paper we consider a systematic expansion of the Hamiltonian in derivatives of the electron field and the strain tensor,26

\[ u_{ij} = \frac{1}{2} (\partial_i \xi_j + \partial_j \xi_i + \partial_i \partial_j h), \quad i, j = x, y, \]  

where \( \xi_i \) and \( h \) are horizontal and vertical displacements respectively. This makes sense in the presence of elastic deformations, where each new derivative of the strain is expected to be suppressed by a factor of order \( O(\alpha / \lambda) \), where \( \lambda \) is the wavelength of the deformation and \( \alpha \) is the lattice constant. As we are interested in a continuum low-energy approximation where electrons behave like Dirac fermions, we will restrict ourselves to terms that are at most linear in the electron momentum \( k \), where \( k \) is measured with respect to a Fermi point. Moreover, we will assume that the system is within the domain of applicability of standard linear elasticity theory and consider only terms linear in the strain tensor. Thus the effective Hamiltonian will be a function of the electron fields \( \psi \) and \( \psi^\dagger \), the strain \( u_{ij} \), and their derivatives. Each expansion will be characterized by \( (n_q, n_k) \), where \( n_q \) and \( n_k \) count the order of the derivatives of the strain and electron fields respectively. Possible extensions of this approach to include nonlinear contributions and optical modes will be discussed in Sec. V.

Any valid effective Hamiltonian must respect all the symmetries of the system. In the case of graphene, these include the point group \( D_{6h} \) of the honeycomb lattice.27 \( D_{6h} \) consists of 24 symmetry operations, and one of them is reflection by the horizontal plane \( \sigma_h \). A first simplification is afforded by the fact that all the ingredients in the effective Hamiltonian are invariant under reflection by \( \sigma_h \). More concretely, electron fields are combinations of \( p_i \) orbitals which are odd under \( \sigma_h \), but only bilinears in the electron field are allowed in the Hamiltonian and these are obviously even. Similarly, vertical atomic displacements \( h \) are odd under \( \sigma_h \), but only the combinations \( (\partial_i h)(\partial_j h) \) enter the Hamiltonian and these are even. As a consequence, we may ignore \( \sigma_h \) as a symmetry and consider \( C_{6v} \) instead of \( D_{6h} \). \( C_{6v} \) has only 12 elements, which include rotations by multiples of \( \pi/3 \) around the \( OZ \) axis and reflections by three vertical planes. Besides the little point group \( C_{3v} \), \( K_1 \) is also invariant under the combined operation \( C_{3v} \theta \), where \( C_2 \) is a rotation by \( \pi \) around the \( OZ \) axis and \( \theta \) is time reversal. Once a Hamiltonian respecting \( C_{3v} \) and \( C_{3v} \theta \) has been constructed around \( K_1 \), time-reversal symmetry, which takes \( K_1 \) into \( K_2 \), can be used to obtain the Hamiltonian at \( K_2 \). This ensures that the total Hamiltonian, which is the sum of the two Hamiltonians around \( K_1 \) and \( K_2 \), respects all the symmetries of the system.

Once we know the set of symmetries to be respected by the interaction terms, the next step is to classify the relevant magnitudes according to their transformation properties. The result is shown in Table VIII in Appendix A, where the relevant objects are assigned irreducible representations of the little point group \( C_{3v} \). As is well known the Fermi surface of the system at half filling consists of six Dirac points located at the corners of the Brillouin zone in momentum space. Only two are nonequivalent, and can be chosen at opposite corners, \( K_2 = -K_1 \). We will study the case where there are no interactions relating the two Fermi points and analyze each of them independently. Then the low-energy description of the electronic excitations around these points is governed by two Dirac Hamiltonians related by time reversal. This is the relevant situation for long-wavelength elastic deformations, and in this case the Dirac points are protected against gap opening by smooth deformations respecting inversion and time-reversal symmetry.28 Then symmetry allowed interactions around \( K_1 \) must be invariant only under the elements of \( C_{6h} \), which leave \( K_1 \) invariant. This is known as the little point group \( C_{3v} \) of \( K_1 \), which is given by \( C_{3v} \). As reviewed in Appendix A, \( C_{3v} \) is a subgroup of \( C_{6h} \) with only six elements: rotations by multiples of \( 2\pi/3 \) around the \( OZ \) axis and reflections by three vertical planes. Besides the little point group \( C_{3v} \), \( K_1 \) is also invariant under the combined operation \( C_{3v} \theta \), where \( C_2 \) is a rotation by \( \pi \) around the \( OZ \) axis and \( \theta \) is time reversal. Once a Hamiltonian respecting \( C_{3v} \) and \( C_{3v} \theta \) has been constructed around \( K_1 \), time-reversal symmetry, which takes \( K_1 \) into \( K_2 \), can be used to obtain the Hamiltonian at \( K_2 \). This ensures that the total Hamiltonian, which is the sum of the two Hamiltonians around \( K_1 \) and \( K_2 \), respects all the symmetries of the system.

III. SYMMETRY ALLOWED TERMS IN THE EFFECTIVE HAMILTONIAN

A. Effective Hamiltonian to first derivative order

The results of following the procedure outlined above and detailed in Appendix A may be summarized in an effective Hamiltonian which contains all the symmetry allowed interactions to first derivative order, i.e., for \( n_q + n_k \leq 1 \). This is given by

\[ H = H_0 + \sum_{i=1}^{6} a_i H_i + \sum_{i=1}^{6} \tilde{a}_i \tilde{H}_i, \]  

where \( H_0 = v_F (\sigma_1 k_x + \sigma_2 k_y) \) and the terms \( H_i \) are given in Table II. The terms \( \tilde{H}_i \) are obtained from those in Table II through the substitution \( u_{ij} \rightarrow \partial_i h \partial_j h \), where \( h \) is the vertical displacement. The reason for the appearance of the extra terms \( \tilde{H}_i \) in the Hamiltonian is that \( \partial_i h \partial_j h \) transforms exactly like \( u_{ij} \)
under all the symmetries of the system. Thus for each invariant written in terms of $u_{ij}$, another one exists with $u_{ij}$ replaced by $\partial_j h \partial_j h$, and the coefficients of $H_1$ and $\hat{H}_1$ have to be determined independently. This will be done in the next section and, for the time being, we will refer to the more familiar $H_1$. At the end of this section we will argue that the effective Hamiltonian (2) probably captures all the experimentally relevant effects due to nonuniform strain.

Equation (2) gives the form of the first-quantized Hamiltonian. The corresponding second-quantized Hamiltonian operator is given by

$$\hat{H} = \int d^2x \psi^\dagger \hat{H}\psi,$$

where the symmetric convention for the derivatives acting on the electron fields is understood, i.e., $\psi^\dagger \partial_i \psi = -i/2(\psi^\dagger \partial_i \psi - \partial_i \psi^\dagger \psi)$. For instance, $\hat{H}_5$ is given by

$$\hat{H}_5 = -\frac{i}{2} \int d^2x u_{ij}(\psi^\dagger \sigma_i \partial_j \psi),$$

where $\partial_j$ acts only on the electron fields. The advantage of using the symmetric derivative convention is that any real expression in the electron momentum $k$, the strain (and its derivatives), and a Hermitian matrix will automatically give rise to a second-quantized Hermitian operator. This simplifies the counting and construction of Hermitian invariants. In this regard, it is important to realize that $(n_q,n_k)$ in Table II gives the orders of the derivatives when terms are written with the symmetric convention. See also comments around Eq. (5) below.

Table II displays all the Hermitian, symmetry-allowed terms of given orders $(n_q,n_k)$ in the derivatives of the electron fields $(n_k)$ and strain $(n_q)$, as indicated in the second column. The remaining columns give their physical interpretation and the relative sign of the couplings at the two nonequivalent Dirac points. In what follows we will comment briefly on the physical significance of the various terms which, with the exception of $H_6$, have already been given in Refs. 19 and 21:

(i) $H_1 = (u_{xx} + u_{yy})I$: This term has the form of a scalar potential $\Phi \sim u_{xx} + u_{yy}$, and was already described in Ref. 5, where the coupling strength was estimated to be of order 4 eV for single layer graphene. Its physical consequences have been explored in Ref. 32.

(ii) $H_2 = (u_{xx} - u_{yy})\sigma_x - 2u_{xy}\sigma_y$: Dirac cone shift in momentum space or $U(1)$ pseudogauge field $(A_x, A_y) \sim (u_{xx} - u_{yy} - 2u_{xy})$. This term corresponds to the well-known elastic pseudogauge fields of the standard tight-binding approach. It has been used in the literature to propose all kinds of strain engineering and to fit experimental measurements of very intense pseudomagnetic fields in corrugated graphene samples. It has also been used to explain data in artificial graphene.\(^ \text{9}\)

(iii) $H_3 = [(u_{xx} - u_{yy})k_x - 2u_{xy}k_y]I$: Dirac cone tilt. This term appears naturally in the description of the two-dimensional organic superconductors\(^ \text{33}\) which are described by anisotropic Dirac fermions. It also arises when applying uniaxial strain in the zigzag direction, a situation that has been discussed at length in the literature\(^ \text{34-37}\).

(iv) $H_4 = (u_{xx} + u_{yy})(\sigma_x k_x + \sigma_y k_y)$: Isotropic position-dependent Fermi velocity.\(^ \text{11}\)

(v) $H_5 = u_{ij}\sigma_{ij}k_j$: Anisotropic position-dependent Fermi velocity.\(^ \text{11}\) This term, together with $H_1$, was predicted to arise within the geometric modeling of graphene based on techniques of quantum field theory in curved space.\(^ \text{10}\) It was later obtained in a tight-binding model by expanding the low-energy Hamiltonian to linear order in $q$ and $\xi$.\(^ \text{11,14}\) It comes together with a new vector field $\Gamma_i$, which will be discussed below. Since the Fermi velocity is the most important parameter in graphene physics, this term affects all the experiments and will induce extra spatial anisotropies in strained samples near the Dirac point.\(^ \text{38-43}\)

(vi) $H_6 = (u_{xx} + u_{yy})(\sigma_x k_x + \sigma_y k_y)$: This is the only term that suggests a new gap-opening mechanism that has not been noticed previously. It can be seen as the Zeeman coupling of pseudospin to the associated pseudomagnetic field $B$ = $\partial_i A_i$.\(^ \text{34}\) The magnitude of this new gap will be estimated in Sec. IV C where we will explore its physical implications.

(vii) To first order in the derivative expansion we can also construct an invariant involving the antisymmetric derivative of the displacement vector $\omega = \partial_x \xi_y - \partial_y \xi_x$:

$$\omega(k_x \sigma_y - k_y \sigma_x) = \omega \epsilon_{ij} k_i \sigma_j,$$

but, as shown in Ref. 14, it can be eliminated by a local rotation of the pseudospinor $\psi \rightarrow \exp(-\frac{i}{2} \omega \sigma_z) \psi$. Thus the effective Hamiltonian (2) does not depend on $\omega$.

Note that the new vector field $\Gamma_i$, which plays the role of the spin connection in the geometric formalism and goes together with the position-dependent Fermi velocity as discussed in Refs. 11 and 14, does not appear explicitly in Table II. However, if one uses integration by parts on (3) to revert $H_5$ to the more common asymmetric convention, the result is

$$\tilde{H}_5 = -i \int d^2x \psi^\dagger \sigma_i \frac{1}{2} \partial_j u_{ij} \psi,$$

where we recognize the contribution $\frac{1}{2} \partial_j u_{ij}$ to the vector field $\Gamma_i$. Similarly, the other piece of $\Gamma_i$ is obtained after integration by parts of $\hat{H}_5$. Thus, even though the symmetric derivative
convention seems to eliminate $\Gamma_i$ from the Hamiltonian, this field will show up in the equations of motion, which involve precisely this integration by parts. This means that $\Gamma_i$ is a relevant field, giving rise to physical effects such as pseudospin precession.\footnote{MAÑES, DE JUAN, STURLA, AND VOZMEDIANO PHYSICAL REVIEW B 88, 155405 (2013)}

We close this subsection with a comment on the last column in Table II. If we assume that Eq. (2) gives the Hamiltonian around the $K_1$ Dirac point, then the Hamiltonian around $K_2$ is obtained by flipping the signs of the couplings $a_i$ and $\bar{a}_i$ according to the last column. This assumes the use of the $(A_1, B_1, B_2, A_2)$ convention for the pseudospinors. In other words, whereas the first component of the pseudospinor around $K_1$ refers to the $A$ sublattice, the first component around $K_2$ refers to the $B$ sublattice. With this convention the unperturbed Hamiltonians $H_0$ are identical around the two Dirac points and the three components of the pseudospin operator—the three Pauli matrices, not just $\sigma_z$—are odd under time reversal. See Appendix A for a detailed explanation.

B. Beyond first derivative order

Equation (2) with Table II gives the most general effective Hamiltonian containing at most one derivative of the electron field or the strain, i.e., for $n_q + n_k \leq 1$. One can easily go to higher derivative orders. For instance, according to the last column in Table I, at order $(2, 0)$ there are two new invariants proportional to the unit matrix and three containing $\sigma_x$ field or the strain, i.e., for $n_q$ in Table II. If we assume that Eq. (2) gives the Hamiltonian around the column in Table I, at order $(2, 0)$ there are two new invariants according to the last column. This assumes the use of the convention seems to eliminate $\Gamma_i$ from the Hamiltonian, this field will show up in the equations of motion, which involve precisely this integration by parts. This means that $\Gamma_i$ is a relevant field, giving rise to physical effects such as pseudospin precession.\footnote{MAÑES, DE JUAN, STURLA, AND VOZMEDIANO PHYSICAL REVIEW B 88, 155405 (2013)}

show this, we first notice that the most general perturbation of the massless Dirac Hamiltonian $H_0$ which is linear in the electron momentum $k$ must take the form

$$\delta H = \alpha_1 \delta \sigma_z + \alpha_2 \delta x + \alpha_3 \delta y + \alpha_4 \sigma_z,$$

where the functions $\alpha_i$ are at most linear in $k$. First, $\alpha_i = \alpha^{(0)}_i + \alpha^{(1)}_i k$. Now, comparing with Table II we have $\alpha^{(0)}_i \sim u_{xx} + u_{yy}$, $\alpha^{(1)}_i \sim u_{xx} - u_{yy}$, etc. The only missing terms are those giving the $O(k)$ contribution to $\alpha_i$. According to Table I, there are two terms of order $(1, 1)$ that contribute to $\alpha^{(1)}_i$ and $\alpha^{(2)}_i$. These are easily constructed with the techniques reviewed in Appendix A, and are given by

$$\epsilon_{ij} k_j \partial_i u_{kk} \sigma_z + \epsilon_{ij} k_i \partial_j u_{kk} \sigma_z.$$  

We note in passing that the first term can be written as $\tilde{\mathcal{A}} \cdot (\tilde{K} \times \vec{V} \Phi)$ and has the form of a pseudospin-orbit coupling. Now, the unperturbed Dirac Hamiltonian $H_0$ plus the two terms in Eq. (7) give a Hamiltonian of the form $H \sim v_F \sigma_i k_i + \sigma_z b_i k_i$, which squares to

$$E^2 = u^2_F k^2 + (b_i k_i)^2$$

and one can see that the effect of the new terms on the spectrum is just a change in the Fermi velocity, which becomes anisotropic and position dependent. In other words, they give higher-order corrections to an effect already accounted for by $H_1$ and $H_2$ at lower order. As these corrections would probably be very hard to measure experimentally, the effective Hamiltonian given by Eq. (2) is, in this phenomenological sense, complete.

We finish this section with a comment on the local rotation $\omega = \partial_x \xi_y - \partial_y \xi_x$. The results of using Eq. (A2) with $u_{1j}$ replaced by $\omega$ are given in Table IV, which shows that only three invariant terms involving $\omega$ can be constructed with $n_q + n_k \leq 2$.

The one of order $(0, 1)$, which is given in Eq. (4), has already been discussed. The two remaining invariants are

$$\left( k_x \partial_x \omega + k_y \partial_y \omega \right) \sigma_z \quad \text{and} \quad 2 \left( \partial_{xy} \omega \right) \sigma_x + \left( \partial_x^2 \omega - \partial_y^2 \omega \right) \sigma_y.$$  

The first one is of order $(1, 1)$ and should be added to the two invariants in Eq. (7). The last one, of order $(2, 0)$, provides an additional correction to the pseudogauge fields. Our previous discussion suggests that the effects of these two terms will be hard to detect experimentally.

IV. GENERALIZED TIGHT-BINDING HAMILTONIAN

In the previous section we have used symmetry arguments to construct the allowed terms in the low-energy Hamiltonian...
in the presence of strain, but symmetry alone cannot fix the values of the coefficients. In this Section we will use a generalized tight-binding (TB) model to estimate the numerical values of the couplings.

Nearest-neighbor (NN) interactions take place only between atoms belonging to different sublattices. As a consequence, the resulting Hamiltonian contains only off-diagonal contributions and misses all the terms proportional to the matrices $I$ and $\sigma_z$. In order to generalize the standard NN-TB model, two new parameters are introduced: $-t_{2}$ is the hopping integral between next-nearest neighbors (NNNs) and $V$ is the contribution of a nearest-neighbor potential to the on-site energy of an electron in a $p_z$ orbital. Recent calculations of the values of these parameters can be found in Ref. 45.

We consider first the simpler case of in-plane strain [$h(\vec{r}) = 0$], and Fourier expand the atomic displacements $\vec{\xi}(\vec{r})$,

$$\vec{\xi}(\vec{r}) = \sum_\vec{q} \xi_\vec{q} e^{i\vec{q} \cdot \vec{r}}$$

with $\vec{\xi}(\vec{q}) = \vec{\xi}(\vec{q})^*$. (10)

The electron Bloch waves are given by

$$\Phi_\vec{k}(\vec{r}) = \frac{1}{\sqrt{N}} \sum_\vec{r} e^{i\vec{k} \cdot (\vec{r} - \vec{r}_1)} \phi(\vec{r})$$

where $\phi(\vec{r})$ denotes a $p_z$ atomic orbital, $\vec{r}_i$ ($i = 1, 2$) are the positions of the two atoms in a reference unit cell, and the sum runs over the $N$ points $\vec{r}_i$ in the Bravais lattice. Denoting by $\vec{v}_n$ and $\vec{w}_n$ the relative positions of nearest- and next-nearest neighbors respectively, the matrix elements of the Hamiltonian

$$\delta H_{ij}(\vec{q}, \vec{k}) = \langle \Phi_i(\vec{k} + \frac{\vec{q}}{2}) | \delta H | \Phi_j(\vec{k} - \frac{\vec{q}}{2}) \rangle$$

are given by

$$\delta H_{11}(\vec{q}, \vec{k}) = -2it_{2} \sum_{n=1}^{6} \xi_\vec{q} \cdot \vec{w}_n e^{i\vec{q} \cdot \vec{K}_1 + \vec{k}} \sin \left(\frac{\vec{q} \cdot \vec{w}_n}{2}\right)$$

$$+ V' \sum_{n=1}^{3} \xi_\vec{q} \cdot \vec{w}_n (e^{i\vec{q} \cdot \vec{q}} - 1)$$

$$\delta H_{12}(\vec{q}, \vec{k}) = -2it_{1} \sum_{n=1}^{3} \xi_\vec{q} \cdot \vec{w}_n e^{i\vec{q} \cdot \vec{K}_1 + \vec{k}} \sin \left(\frac{\vec{q} \cdot \vec{w}_n}{2}\right),$$

(13)

where $-t_1$ is the usual hopping integral between NNs, $V' \approx \partial(\log t_{1})/\partial(r \log r)$, and the primes denote derivatives $\partial/\partial r$ that are always evaluated at the equilibrium positions. $\delta H_{21}$ and $\delta H_{22}$ are obtained from $\delta H_{11}$ and $\delta H_{12}$ respectively by making the replacement $\vec{v}_n \rightarrow -\vec{v}_n$. Note the symmetric split of the phonon momentum $q$ among the incoming and outgoing electrons in (12), which in position space implies the symmetric derivative convention used in the last section. Equation (13) is valid to all orders in the electron and phonon momenta $k$ and $q$, and the generalization to include any number of neighbors is obvious: one just has to add new terms, with $\vec{v}_n$, $\vec{w}_n$ replaced by the vectors corresponding to the new neighbors. See Appendix B for our conventions and details on the derivation of Eq. (13).

Expanding (13) to the required powers of $\vec{q}$ and $\vec{k}$, and comparing with Table II we get the values for the in-plane electron-strain couplings listed in Table V. Note that these values do not include possible corrections originating from the deformation of the lattice vectors.\textsuperscript{12-14} The reason is that we are using equilibrium atomic positions in our Bloch functions (11) or, in the language of Ref. 14, we are working in the “crystal frame.” The contributions from the deformation of the lattice vectors,\textsuperscript{12,13,46,47} also known as “lab frame effects,”\textsuperscript{14} will be incorporated in Sec. IV B.

The values of $a_2$, $a_3$, and $a_5$ can be obtained within the usual NN-TB model and have been known for some time. As the terms $\tilde{H}_i$ vanish for $h = 0$, in order to compute the corresponding coefficients $\tilde{a}_i$ we must consider off-plane strains.

\section{A. Tight-binding computation for off-plane strains}

The usual assumption when dealing with nonplanar strains is that off-plane atomic displacements $h(\vec{r})$ enter the Hamiltonian only through the combination $u_i = (\partial h / \partial x_i + \partial h / \partial y_i + \partial h / \partial z_i)/2$. The rationale is that the distance between two nearby points is given by $ds^2 = (\delta_{ij} + 2u_{ij})dx_i dx_j$, where $d x_i$ is the difference between the equilibrium coordinates of the two points. However, this is justified if the matrix elements between orbitals belonging to different atoms depend only on the distance, which is valid for $s$ orbitals, but integrals involving $p_z$ orbitals are nonisotropic. To be concrete, whereas integrals involving two $s$ orbitals are parametrized by a single function of the distance, usually denoted $(ss\sigma)$, two independent functions are required in the case of $p$ orbitals. These are denoted $(pp\sigma)$ and $(pp\pi)$; see Fig. 1. For flat graphene, only $(pp\pi) = -t_1$ is relevant, and in this respect $p_z$ orbitals behave just like $s$ orbitals.

However, in the presence of curvature the two $p_z$ orbitals are no longer parallel.\textsuperscript{48} In terms of $(pp\pi) \equiv f_p(r)$ and $(pp\pi) \equiv f_p(r)$, one can use linearity to show that the matrix element is then given by

$$\langle \Phi_i | H | \Phi_2 \rangle = \langle \hat{\pi}_1 \cdot \hat{\pi} | \hat{\pi}_2 \cdot \hat{\pi} \rangle f_p(r)$$

$$+ \langle \hat{\pi}_1 - (\hat{\pi}_1 \cdot \hat{\pi}) \hat{\pi} | \hat{\pi}_2 - (\hat{\pi}_2 \cdot \hat{\pi}) \hat{\pi} \rangle f_p(r).$$

(14)

\begin{table}
\centering
\caption{Crystal frame couplings for $\{H_i\}$, $\sigma$ is the distance between NNs.}
\begin{tabular}{ccc}
\hline
\text{Index} & \text{Expression} \\
\hline
1 & $\frac{1}{2} t_1 a^3 + \frac{1}{2} V' a$ \\
2 & $\frac{\beta}{2} \gamma$ \\
3 & $-\frac{1}{2} t_1 a^2$ \\
4 & $\frac{\beta^2}{2} \gamma$ \\
5 & $\frac{\gamma}{2} v_F$ \\
6 & $\frac{\gamma}{2} V' a^2$ \\
\hline
\end{tabular}
\end{table}

\begin{figure}
\centering
\includegraphics[width=0.5\textwidth]{Fig1.png}
\caption{(Color online) Left: The two independent, $r$-dependent integrals $(pp\sigma)$ and $(pp\pi)$ for $p_z$ orbitals. For flat graphene, only the first one is relevant. Right: For graphene with curvature, $p_z$ orbitals are no longer parallel.}
\end{figure}
where \( \hat{a}_i \) are unit vectors parallel to the \( p \) orbitals, which may be assumed to be perpendicular to the surface. This has a rather involved dependence, not only on \( r \), but also on the angles. Thus, the assumption that the Hamiltonian depends on \( h \) only through Eq. (1) is not valid in general for curved graphene.

On the other hand, in order to have curvature we need non-vanishing second derivatives of \( h \). This means that couplings involving only first derivatives of \( h \) are independent of the \((pp\tau)\) integrals and, as a result, their dependence on off-plane strains is only through \( u_{ij} \). As only \( \hat{H}_0 \) and \( \hat{H}_5 \) involve second derivatives of \( h \), we see that, with the usual approximations implicit in TB, \( \hat{a}_i = 0 \) for \( i = 1, \ldots, 5 \). Expanding Eq. (14) to the appropriate order it is easy to see that the first nonvanishing contribution is proportional to second derivatives of the strain and, as a consequence, the coefficient \( \delta a_6 \) vanishes. This is true in the reference system of the perfect lattice (crystal frame). Frame effects will be discussed in the next subsection.

### B. Lab frame effects

Lab frame effects are the result of the change from crystal to laboratory coordinates, as was discussed in detail in Ref. 14. As a consequence, new terms independent of the TB couplings appear in the Hamiltonian. Crystal coordinates \( \{x\} \) are just the atomic equilibrium positions. If we define the laboratory coordinates \( \{y_j\} \) as the horizontal projections of the out-of-equilibrium positions, \( y_j = x_j + \xi_j(x) \), then a change of variables in the continuum Hamiltonian gives the result

\[
\hat{H}_{\text{lab}} = \hat{H}_{TB} + \hat{H}_{\text{Geom}},
\]

where \( \hat{H}_{TB} \) is the Hamiltonian in the crystal frame and

\[
\hat{H}_{\text{Geom}} = v_F \int d^2x \tilde{u}_{ij}(\psi^\dagger \sigma_k \frac{\partial}{\partial x} \psi)
\]

with \( \tilde{u}_{ij} = \frac{1}{2} (\partial_i \xi_j + \partial_j \xi_i) \). Comparing with Table II, we see that \( \hat{H}_{\text{Geom}} \) is proportional to \( \hat{H}_5 \) with \( u_{ij} \) replaced by \( \tilde{u}_{ij} \). Thus both \( a_5 \) and \( \delta a_5 \) are corrected to compensate for the absence of the nonlinear piece in \( \tilde{u}_{ij} \):

\[
\delta a_5 = -\delta a_5 = v_F.
\]

We have summarized our knowledge of the laboratory couplings in Table VI.

### C. Pseudo-Zeeman term

As discussed in Sec. III, \( \hat{H}_6 \) is a new term which describes the direct coupling of the \( z \) component of pseudospin to the pseudomagnetic field \( B \). This term plays the role of a mass in the Dirac fermion effective theory and opens a gap in the spectrum. This mechanism is different from the various proposals of gap opening by strain in the literature, such as the gap associated to the the Landau levels, superlattices, or by merging of the Fermi points by strain. It is analogous to the one obtained by an on-site potential that is opposite in the two sublattices (note that the required strain breaks inversion symmetry as well), but offers the additional advantage of being tunable by the externally induced strain. This type of diagonal terms coming from strain has been recently discussed in Ref. 47 in an approach which uses directly the atomic displacements without reference to continuous elasticity theory.

The order of magnitude of this gap may be estimated with the case of a ripple of moderate strain with height \( h = 5 \) \( \text{Å} \) and width \( l = 25 \) \( \text{Å} \), which gives a pseudomagnetic field of

\[
B \approx \frac{1}{l} \frac{h^2}{l^2} = 0.0016 \text{ Å}^{-1},
\]

and an energy gap of the order of

\[
E_{\text{Zeeman}} = 3/8V' a^2 B \approx 7 \text{ meV},
\]

were we have taken the value \( V' = 6 \) eV/\( \text{Å} \) from Ref. 20. The presence of this new term has several interesting implications. As it is known, the orbital coupling of elastic pseudomagnetic fields comes with opposite signs in the two Fermi points so that the combined effect of real and pseudomagnetic fields gives rise to valley separation effects, and the same is expected for the Zeeman coupling. Indeed, in the presence of high magnetic fields, the zeroth Landau level will be split by a controlled pseudo-Zeeman coupling and induce valley polarization. In addition to providing a measurement of the coefficient \( a_6 \), this may help to understand the origin of the observed interaction-induced splittings—which can be of similar magnitude at moderate field—as by studying the dependence of the gap with the pseudofield, and the competition with the real Zeeman coupling. As a related effect, the in-plane distortion that generates this splitting may be induced spontaneously via a Peierls instability, by the same mechanism as the out-of-plane distortion studied in Ref. 63.

## V. SUMMARY AND DISCUSSION

In this work we have used a symmetry approach to construct all possible terms affecting the low-energy properties of graphene in the presence of nonuniform lattice deformations. We have limited our analysis to linear elasticity theory and assumed that the two Fermi points do not mix, which is a sensible assumption for reasonably smooth strains.

As we are primarily interested in the effects of nonuniform strain, we have set up a derivative expansion of the effective Hamiltonian and used group theory techniques to obtain the number of independent couplings at each derivative order. This procedure guarantees that no relevant interactions are left out. Then we have constructed the interactions in a completely model independent way.

After a careful analysis of the physical effects of the interactions and the properties of the derivative expansion, we have argued that the first-order effective Hamiltonian in Eq. (2) is “phenomenologically complete,” in the sense that any
as mentioned in Sec. II, as long as we neglect interactions between the two inequivalent Dirac points we can restrict ourselves to the symmetries that leave $K_1$ invariant, i.e., to the little group of $K_1$. The little point group $C_{3v}$ consists of six elements: the identity operation $E$, two $\pm 2\pi/3$ rotations $C_3^\pm$ around the $OZ$ axis and three reflections $\sigma_v$ by vertical planes. Transformation properties under $C_{3v}$ are classified by three irreducible representations (IRs): $A_1$ and $A_2$ are one dimensional, whereas $E$ is two dimensional. Their character tables together with their products are given in Table VII.

Table VIII gives the transformation properties of all the ingredients used in the construction of the effective Hamiltonian for strained graphene. For the sake of completeness, we have included the antisymmetric part of $\delta_{ij}$, which represents a local rotation. Note that the transformation properties of the Pauli matrices follow from those of the electronic states. More concretely, the two components of the electron field $(\psi_1, \psi_2)$ transform according to the irreducible representation $E$. Then the set of four $2 \times 2$ Hermitian matrices belongs to the reducible representation $E \times E$, which decomposes according to

$$E \times E = A_1(1) + A_2(\sigma_z) + E(\sigma_x, \sigma_y).$$

Group theory can now be used to obtain the number of independent terms in the effective Hamiltonian at order $(n_q, n_k)$. The basic formula is

$$n = \frac{1}{N} \sum_g \chi_T(g),$$

where $n$ is the number independent invariants, $N$ is the number of elements $g$ in the group, and $\chi_T(g)$ is the character of $g$ in the representation $T$ associated to the interaction term. The character $\chi_T(g)$ is generally obtained as the product of the characters of the representations corresponding to the different components of the interaction term. As an example, assume that we want to know the number of independent terms of order

**Table VIII.** Transformation properties under the little group of $K_1$. The antisymmetric part of $\delta_{ij}$ is given by the local rotation $\omega = \delta_{ij} \xi_j - \delta_{ji} \xi_i$.

</tbody>
</table>
(n_x, n_y) = (0, 1) containing the matrices \( \sigma_x, \sigma_y \). This involves the quantities \( u_{ij}, k_i, \) and \( \sigma_i \), which according to Table VIII belong to the representations \( A_1 + E, E, \) and \( E \) respectively. Thus

\[
\chi_T = (\chi_{A_1} + \chi_E) \times \chi_E \times \chi_E. \tag{A3}
\]

which implies

\[
\chi_T(E) = 12, \quad \chi_T(C_3^2) = \chi_T(\sigma_i) = 0. \tag{A4}
\]

Then Eq. (A2) gives \( n = 2 \).

Note that according to Table VIII, both \( \sigma_z \) and the derivatives \( \partial_i \) acting on the strain are odd under \( \theta C_2 \). Thus, terms proportional to the matrices \( \{1, \sigma_x, \sigma_y\} \) must contain an even number of derivatives of the strain, whereas this number must be odd for terms proportional to \( \sigma_z \). The results of using this method for \( n_x + n_y \leq 2 \) are summarized in Table I (Sec. II). The number of invariants involving \( \omega \) instead of \( u_{ij} \) is given in Table IV.

Invariant interactions, which by definition transform like \( (A_1, +) \), can be obtained by using the following composition rules for the IRs of \( C_{3v} \):

\[
A_1(a) \times E(b_1, b_2) = E(ab_1, ab_2),
\]

\[
A_2(a) \times E(b_1, b_2) = E(ab_2, -ab_1),
\]

\[
E(a_1, a_2) \times E(b_1, b_2) = A_1(a_1 b_1 + a_2 b_2) + A_2(a_1 b_2 - a_2 b_1) + E(a_1 b_2 - a_2 b_1) - a_1 b_2 - a_2 b_1) . \tag{A5}
\]

For one-dimensional IRs, we have \( A_1(a) \times A_1(b) = A_1(ab), \) \( A_2(a) \times A_2(b) = A_1(ab), \) and \( A_1(a) \times A_2(b) = A_2(ab). \) Several examples of the use of these relations are given at the end of this Appendix.

Once an interaction term has been constructed around \( K_1 \), we can use the time-reversal operation \( \theta \) to construct the corresponding interaction around the other Dirac point \( K_2 \). Time reversal acts by complex conjugation, and its action on the different objects is given in the left-hand side of Table IX for the the usual \( (A_1, B_1, A_2, B_2) \) sublattice convention.

As an example, the Dirac Hamiltonian \( k_i \sigma_x + k_j \sigma_y \) at \( K_2 \) is given by

\[
\theta : k_i \sigma_x + k_j \sigma_y \rightarrow -k_i \sigma_x + k_j \sigma_y. \tag{A6}
\]

In order to compare interaction Hamiltonians at the two Dirac points, we have to take into account that even \( H_0 \) differs by the sign of \( k_i \). This fact, which makes a direct comparison awkward, can be avoided by a change of basis at \( K_2 \). Conjugation of the Pauli matrices by \( \sigma_z \) yields

\[
\sigma_z(1, \sigma_x, \sigma_y, \sigma_z) \sigma_z = (1, -\sigma_x, \sigma_y, -\sigma_z) \tag{A7}
\]

and now \( H_0 \) takes the same form at the two Dirac points

\[
\sigma_z(-k_i \sigma_x + k_j \sigma_y) \sigma_z = k_i \sigma_x + k_j \sigma_y \tag{A8}
\]

Conjugation by \( \sigma_z \) changes the sublattice convention to \( (A_1, B_1, B_2, A_2) \). This is summarized in the right-hand side of Table IX, which can be used to obtain the Hamiltonian at \( K_2 \) after conjugation by \( \sigma_z \). Note that now all three Pauli matrices are odd under time reversal.

We finish this Appendix with a few examples:

(i) The fourth line in Table VIII together with the third line in Eq. (A5) show that the Dirac Hamiltonian \( H_0 = k_i \sigma_x + k_j \sigma_y \) is invariant. Concretely,

\[
E(k_i, k_j) \times E(\sigma_z, \sigma_z) = A_1(k_i \sigma_x + k_j \sigma_y) + \ldots \tag{A9}
\]

(ii) The fourth line in Table VIII together with the third line in Eq. (A5) imply that \( H_2 = (u_{xx} - u_{xy}) \sigma_x - 2u_{xy} \sigma_y \) is invariant. Using Table IX to obtain \( H_2 \) at \( K_2 \) gives

\[
(u_{xx} - u_{xy}) \sigma_x - 2u_{xy} \sigma_y \rightarrow -(u_{xx} - u_{xy}) \sigma_x + 2u_{xy} \sigma_y, \tag{A10}
\]

showing that pseudogauge fields have opposite signs at the two Dirac points.

(iii) The fourth and fifth lines in Table VIII together with the first line in Eq. (A5) show that \( \partial_i (u_{xx} - u_{yy}) + 2\partial_i u_{xy} \) transforms according to \( (A_2, \ldots) \). Concretely,

\[
E(\partial_i, \partial_i) \times E(u_{xx} - u_{yy}, -2u_{xy}) = A_2[\partial_i (u_{xx} - u_{yy}) + 2\partial_i u_{xy}] + \ldots \tag{A11}
\]

Then \( A_2 \times A_2 = A_1 \) and the third line in Table VIII imply that \( H_0 = [\partial_i (u_{xx} - u_{yy}) + 2\partial_i u_{xy}] \sigma_z \) is invariant (Zeeman coupling for pseudospin).

**APPENDIX B: GENERALIZED TIGHT-BINDING MODEL**

In this Appendix we fix our conventions and give details on the tight-binding model used to compute the coupling constants. We choose a coordinate system such that the vectors \( \vec{v}_n \) to the three NNSs are given by

\[
\vec{v}_1 = a(0, 1), \quad \vec{v}_2 = -\frac{a}{2}(\sqrt{3}, 1), \quad \vec{v}_3 = \frac{a}{2}(\sqrt{3}, -1), \tag{B1}
\]

where \( a \) is the distance between NNSs. The vectors to the six NNNs are given by

\[
\vec{w}_1 = -\vec{w}_4 = -a(\sqrt{3}, 0), \quad \vec{w}_2 = -\vec{w}_5 = -\frac{a}{2}(\sqrt{3}, 3),
\]

\[
\vec{w}_3 = -\vec{w}_6 = a(\sqrt{3}, -3) \tag{B2}
\]

and the Fermi points are located at \( K_1 = -\vec{K}_2 \) (\( \frac{4a}{\sqrt{3}} \) NNN).

A general displacement

\[
\vec{\xi}(\vec{r}) = \sum_{\vec{q}} \vec{\xi}(\vec{q}) e^{i\vec{q} \cdot \vec{r}} \quad \text{with} \quad \vec{\xi}(-\vec{q}) = \vec{\xi}(\vec{q})^* \tag{B3}
\]

induces a change in the vectors that go from an atom at position \( \vec{r} + \vec{r}_1 \) to its nearest neighbors

\[
\delta \vec{v}_n = \sum_{\vec{q}} \vec{\xi}(\vec{q}) e^{i\vec{q} \cdot (\vec{r} + \vec{r}_1)} [e^{i\vec{q} \cdot \vec{r}_1} - 1], \tag{B4}
\]
with a similar expression for $\delta \tilde{u}_n$. To linear order in $\tilde{q}$, this induces a change in the NN hopping integral,

$$
\delta t_1(\tilde{q}) = \tilde{V}_{11} - \tilde{V}_{1n} = \tilde{v}_n \delta \tilde{v}_n - 1 \tag{B5}
$$

with analogous expressions for $\delta t_2$ and $\delta V$. Then, substituting (B5) into

$$
\delta H_{12}(\tilde{q}, \tilde{k}) = \left( \Phi_1 \left( \tilde{k} + \frac{1}{2} \tilde{q} \right) \delta H \Phi_2 \left( \tilde{k} - \frac{1}{2} \tilde{q} \right) \right)
$$

we get

$$
\delta H_{12}(\tilde{q}, \tilde{k}) = -\frac{1}{N} \sum_{\tilde{i}, \tilde{n}} \delta t_1(\tilde{q}) e^{-i\tilde{q} \cdot (\tilde{k} + \tilde{i})} e^{i\tilde{k} \cdot \tilde{v}_n} \tag{B6}
$$

and doing the sum over the Bravais lattice vectors $\{\tilde{i}\}$ yields

$$
\delta H_{12}(\tilde{q}, \tilde{k}) = -2i\tilde{q} \cdot \sum_{n=1}^{3} \tilde{v}_n e^{i\tilde{k} \cdot \tilde{v}_n} \sin \left( \frac{\tilde{q} \cdot \tilde{v}_n}{2} \right) \tag{B7}
$$

The same method is used to obtain the other matrix elements.

---
