Motivated by recent experimental observations of Tongay et al. [Nano Lett. 12, 5576 (2012)] we show how the electronic properties and Raman characteristics of single layer MoSe$_2$ are affected by elastic biaxial strain. We found that with increasing strain: (1) the $E'$ and $E''$ Raman peaks ($E_{2g}$ and $E_{1g}$ in bulk) exhibit significant redshifts (up to $\sim$30 cm$^{-1}$), (2) the position of the $A'_1$ peak remains at $\sim$180 cm$^{-1}$ ($A_{1g}$ in bulk) and does not change considerably with further strain, (3) the dispersion of low energy flexural phonons crosses over from quadratic to linear, and (4) the electronic band structure undergoes a direct to indirect band gap crossover under $\sim$3% biaxial tensile strain. Thus the application of strain appears to be a promising approach for a rapid and reversible tuning of the electronic, vibrational, and optical properties of single layer MoSe$_2$ and similar MX$_2$ dichalcogenides.

I. INTRODUCTION

The discovery of graphene$^{1,2}$ is expected to play an important role in future nanoscience and nanotechnology applications. Recent advances in nanoscale growth and mechanical exfoliation techniques have led not only to the fabrication of high-quality graphenes but also the emergence of several new classes of two-dimensional (2D) structures such as ultrathin transition metal dichalcogenides (TMDs). Just like graphene TMDs have hexagonal crystal structure composed of layers of metal atoms (M) sandwiched between layers of chalcogen atoms (X) with stoichiometry MX$_2$. TMDs have electronic semiconducting or metallic properties and most of bulk TMDs possess indirect band gaps of the order 1–2 eV.$^3$ The synthesis of several TMDs has been realized experimentally$^4–7$ and of several TMDs has been reported theoretically$^8–7$. Recent studies of various single layer dichalcogenides were recently reported.$^8–7$ Recent studies of several semiconducting TMDs such as MoS$_2$, WS$_2$, MoTe$_2$, and MoSe$_2$ have shown that the band gap increases and transforms to a direct band gap with decreasing number of layers.$^7,9–11$ These sizable band gaps make them well suited for electronic applications such as transistors, photodetectors, and electroluminescent devices. Another unique feature of two-dimensional ultrathin materials is the possibility to apply large reversible elastic strain. It has been shown that graphene can be strained up to 20% of its ideal structure with only small changes in its electronic band structure, which is in contrast to TMDs.$^{12–15}$

The most recent efforts have been directed towards the synthesis and manipulation of molybdenum diselenide (MoSe$_2$) single layers. In addition to preliminary reports on synthesis of few-layer MX$_2$ structures,$^{16,17}$ Tongay et al.$^{12}$ demonstrated that a single layer of MoSe$_2$ possesses a direct optical gap of 1.55 eV and exhibits good thermal stability.$^{18}$ However, to our knowledge, no research exists addressing the question of how electronic properties and lattice dynamics of single layer MoSe$_2$ are affected by strain. In the present work we investigate the effect of biaxial strain on the electronic and vibrational properties of single layer MoSe$_2$ structures. Our calculations revealed that applying biaxial strain is able to tune the Raman characteristics and electronic band structure of single layer MoSe$_2$. We expect that this study will offer new opportunities for strain-engineered nanoscale optoelectronic device applications.

II. COMPUTATIONAL METHODOLOGY

Calculations of physical properties of equilibrium and strained structures were carried out in the framework of density functional theory (DFT), using the plane-wave self-consistent field (PWSCF) code as implemented in the QUANTUM-ESPRESSO package.$^{19}$ The generalized gradient approximation (GGA) of Perdew-Burke-Ernzerhof (PBE) was used for the exchange-correlation potential.$^{20}$ A plane-wave kinetic energy cutoff of 40 Ry and density cutoff of 400 Ry were used. Brillouin zone integration was performed using a shifted $27\times27\times1$ Monkhorst-Pack mesh.$^{21}$ To eliminate the interaction emerging from periodic boundary conditions calculations are performed with a large unit cell including 12 Å vacuum space between adjacent MoSe$_2$ single layers. Ground states and total energies of all systems were obtained after full geometry relaxation with forces on the atoms smaller than 0.02 eV/Å. Phonon frequencies and phonon eigenvectors were calculated in a $4\times4\times1$ $\mathbf{q}$ grid using the density functional perturbation theory (DFPT).$^{22}$

III. RESULTS AND DISCUSSION

A. Single layer MoSe$_2$

Atomically thin MoSe$_2$ is the most recently synthesized member of the ultrathin transition metal dichalcogenides. A single layer structure of MoSe$_2$ can be viewed as a three-layer stacking of Mo and Se atoms, wherein molybdenum atoms are sandwiched between layers of trigonally arranged selenium atoms. In configurations, known as $1H$ structure, each Mo atom is coordinated to six Se atoms. In the equilibrium geometry of the single layer MoSe$_2$, the Mo-Se distance, the
The energies are relative to the Fermi level (i.e. $E_F$). Comparison of the band edges calculated by GGA, GGA + SO, and displacement directions of Raman-active modes. Inset: Side view of atomic structure of MoSe$_2$. (b) Electronic band structure of monolayers are quite stable. Having lattice constant 3.12 Å, MoSe$_2$ has a larger atomic Se-Se distance, and the lattice constant of the hexagonal unit cell are calculated to be 2.528, 3.293, and $|a| = 3.321$ Å, respectively. Thus, in comparison with single layer MoS$_2$ having lattice constant 3.12 Å, MoSe$_2$ has a larger atomic structure due to the larger atomic radius of the Se atoms. In Fig. 1(a) we present the calculated phonon dispersion and vibrational characteristics of Raman-active modes of single layer MoSe$_2$. It is seen that the frequencies of all phonon branches in the whole Brillouin zone have positive values, i.e., MoSe$_2$ crystal can remain stable by generating the required restoring force against atomic distortions. Although the synthesis of single layers of MoSe$_2$ have been achieved only on various substrates so far, energy optimization and phonon dispersion calculations show that freestanding MoSe$_2$ monolayers are quite stable.

The calculated band structure shown in Fig. 1(b) shows that the single layer MoSe$_2$ is a semiconductor with a direct band gap at the $K$ high symmetry point. The top of the valence band is at the $\Gamma$ point when including spin-orbit (SO) interactions. Interestingly, LDA predicts that single layer MoSe$_2$ is an indirect semiconductor where the top of the valence band is at the $K$ point, and the bottom of the conduction band is found to be between the $\Gamma$ and $K$ points. It appears that the physically correct description of single layer MoSe$_2$ structure that was reported experimentally as a semiconductor$^{18}$ with a direct band gap is achieved by using the GGA functionals. Therefore, in the rest of our study PBE calculations will be employed.

Although our PBE calculation captures the qualitative nature of the band edge states it underestimates the band gap. To correct the band gap we use the $G_0 W_0$ approximation$^{23-25}$ as implemented in the VASP package.$^{26,27}$ It was shown before that this kind of calculation has to be converged with respect to the vacuum spacing.$^{28,29}$ We calculate the quasiparticle shifts using $(12 \times 12 \times 1)$ $k$-point grid with vacuum spacings of 15, 20, 25, and 30 Å and then extrapolate them to infinity in a similar fashion as done in Ref. 28. Our $G_0 W_0$ calculation results in a band gap value of 2.33 eV. Note that excitonic effects are pronounced in 2D materials as MoSe$_2$ and we need to calculate the binding energy of the exciton in order to estimate the optical gap. Due to the parabolic shape of the conduction and valence bands, we assume that the exciton has the Mott-Wannier character and the effective mass approximation can be used. Hole and electron effective masses calculated from the band structure are $m_e^* = 0.65$ and $m_h^* = 0.53$ (in units of electron mass). Moreover, we account for the effective electron-hole interaction of the system using the model introduced by Cudazzo et al.$^{34}$ Using parameters reported by Ref. 30 we find the binding energy of the exciton 0.7 eV, which is in agreement with the value obtained by solving the Bethe-Salpeter equation. Combining this with our result from $G_0 W_0$ calculation we estimate the optical gap to be 1.63 eV, which is close to the reported experimental value of 1.56 eV.

B. Lattice dynamics and phonon softening

While bulk MoSe$_2$ crystal has the $D_{6h}$ point group symmetry, it turns into $D_{3h}$ for a single layer structure. Just like in MoS$_2$, lattice vibrations of single layer MoSe$_2$ is characterized by nine phonon branches including three acoustic and six optical branches. Analysis of lattice dynamics shows that the decomposition of the vibration representation of optical modes at the $\Gamma$ point is $\Gamma = 2E'' + A1'' + 2E' + A2'$. While LA and TA acoustic branches have linear dispersion, the frequency of the out of plane flexural (ZA) mode has a quadratic dispersion in the vicinity of $q = 0$. Near to the $\Gamma$ point the in-plane sound velocity of the LA and TA modes are found to be $1.5 \times 10^3$ and $0.9 \times 10^3$ m/s, respectively. It
is also seen that differing from graphene’s phonon dispersion the acoustic and optical modes are well separated from each other. Differing from MoS2 and WS2 structures in which the $A_1'$ mode is the highest Raman-active mode, in MoSe2 the $A_1'$ mode is located in between the $E'$ and $E''$ modes. In Fig. 1(a) the atomic displacements of the Raman-active modes are presented. Interestingly, although recent Raman spectroscopy measurements of Tongay et al.\textsuperscript{15} revealed that only one characteristic Raman peak of single-layer MoSe$_2$ $E_{2g}$ is observable at 240 cm$^{-1}$, our symmetry analysis predicts the existence of two more Raman-active modes. Significantly decreased intensity of Raman peak around 290 cm$^{-1}$ can be explained by considering the coupling of in-plane counterphase vibration of MoSe$_2$ with the SiO$_2$/Si substrate. Moreover, in experiment the disappearance of $E''$ ($E_{1g}$ in bulk) Raman shift around 170 cm$^{-1}$ is due to the inactivity of this vibrational mode to normally incident light.

Recent experiments on graphene and other few-layer materials have revealed that the application of biaxial and uniaxial tensile stress is possible by using flexible substrates. We will investigate now how the lattice dynamics of single layer MoSe$_2$ is affected by biaxial strain.

Figure 2 shows phonon dispersion curves and the evolution of Raman peaks as a function of applied strain. Below 1% strain, the $E'$ branch of single layer MoSe$_2$ experiences $\sim$10 cm$^{-1}$ softening which is larger than that of the $E_g$ mode (diatomic corresponding to $E'$) of graphene.\textsuperscript{36–38} It is seen that the low-energy flexural phonons ($Z_A$) of unstrained single layer MoSe$_2$ turns almost in a linear dependence under 7% strain. Such a change in phonon dispersion implies a significant decrease in scattering of electrons by the flexural phonons and an increase in electron mobility for strained MoSe$_2$. For the $E'$ mode there is a small splitting at the $\Gamma$ point, as in slightly polar materials such as MoS$_2$ and WS$_2$.\textsuperscript{35} It is also seen that due to the weakening of the covalent bonds under strain the $E'$ and $E''$ modes (that correspond to the $E_{1g}$ and $E_{2g}$ in bulk MoSe$_2$, respectively) exhibit significant redshifts of about $\sim$30 cm$^{-1}$. Especially, at the $K$ point, the highest optical mode dips even below the band corresponding to the $E'$ mode. Another remarkable point is the $A_1'$ mode (corresponding to the $A_{1g}$ in bulk) that vibrates perpendicular to the applied strain which experiences a smaller softening and is almost pinned to $\sim$231 cm$^{-1}$ for strain values higher than 1%. Similar direction-dependent softening behavior was observed for various types of materials.\textsuperscript{39,40}

C. Strain-induced direct-to-indirect band gap crossover

In addition to strain-induced changes in the lattice dynamics, the electronic properties of single layer MoSe$_2$ may exhibit surprising deviations. Existence of a band gap even in the monolayer structure shows strong bonding nature and the covalent character of MoSe$_2$ layers. Though the covalent bonds formed from valance electrons of Mo and Se atoms are not broken by elastic strain, the strength of the bond is weakened with the increasing distance. Therefore band energies and dispersion can be expected to be strongly dependent on tensile strain. Evolution of the electronic band dispersion under finite biaxial strain ($\epsilon = 1$–7%) is shown in Fig. 3. It is clearly seen that the band edges at the $\Gamma$ and $K$ symmetry points are influenced significantly by biaxial tensile strain. Up to 3% strain, single layer MoSe$_2$ remains a direct band gap semiconductor with both the top of the valence band and the bottom of the conduction band located at the $K$ point. However, when $\sim$3% strain is applied, as a result of the band shifting at the $K$ point, two valence band edges with the same energy appear in the
located (between \( /Gamma1 \) and \( K \)). In addition, band edges of MoS\(_2\) also experience similar conduction band at the \( K \) point. Moreover, the second conduction band edge accompanied by the lowering of the conduction band dip at \( /Gamma1 \) and \( K \) very close to the dip of the conduction band at the \( K \) point moves upwards in energy. In addition, band edges of MoS\(_2\) also experience similar effects with increasing tensile strain.\(^{12,13}\) The evolution of direct (\( K \rightarrow K \)) and indirect (\( K \rightarrow /Gamma1 K \) and \( /Gamma1 \rightarrow K \)) energy band gaps under tensile stress are presented in Fig. 4(a-b). Both direct and indirect band gaps decrease monotonically with increasing strain, however the rate of decrease is faster for the indirect band gap. Note that the variation of band gaps with increasing strain has the same qualitative behavior for PBE, PBE + SO, and PBE + \( G_0 W_0 \) calculations (see Fig. 4(c)). Although, the effect of spin-orbit coupling is significant, the evolution of the gap with applied strain and other properties are clearly captured by PBE calculation. We predict that the direct-to-indirect crossover takes place at \( 3–4\% \) strain.

As a consequence of the strain-dependent transition of the valence band edge from the \( K \) to \( /Gamma1 \) point the effective mass of the holes (and electrons) propagating through the single layer MoSe\(_2\) lattice changes dramatically. From Fig. 4(b) it is seen that while the mass of the electrons at the band edge does not change notably, the hole mass shows significant deviations under strain. Since the valence band edge is sharpened by biaxial strain, the effective mass of the holes is decreased and after the band gap crossover holes belong to the uppermost valence band at the \( /Gamma1 \) point inversely affected by increasing strain. Note that the holes under \( 7\% \) strain are \( 2 \) times heavier than that for unstrained single layer MoSe\(_2\).

In summary, motivated by the recent experimental study of Tongay \textit{et al.}\(^{18}\) on single layer MoSe\(_2\) we investigated the electronic properties and lattice dynamics of single layer MoSe\(_2\) as a function of biaxial strain. We showed that GGA describes more accurately the electronic structure of single layer MoSe\(_2\) and that LDA predicts the wrong nature of the band gap. We found that monolayer MoSe\(_2\) has four Raman-active characteristic modes: Among these, the modes having counterphase in-plane motion are significantly modified by strain and they soften by increasing strain. Redshift in the position of these resonant Raman peaks are predicted to be \( \sim 30 \) \( \text{cm}^{-1} \). However the \( A_{1g} \) branch (corresponds to the \( A_{1g} \) in bulk) is negligibly influenced by strain. Moreover, the linear dispersion of flexural mode in strained MoSe\(_2\) implies a reduced scattering of electrons from these \( ZA \) phonons. Our findings also revealed that the electronic band structure of single layer MoSe\(_2\) also undergoes substantial changes under biaxial tensile strain. While the direct band gap linearly decreases up to \( \sim 3\% \) tensile strain, a direct to indirect band gap crossover occurs when strain is further increased. Moreover the appearance of a positive curvature at the \( K \) point in the phonon spectra and possible metallicity for higher strain values suggests superconductivity in highly strained single layer MoSe\(_2\). Our findings indicate that the band gap of single layer MoSe\(_2\) can be tuned reversibly by biaxial strain and is able to capture a broad range of the solar spectrum.
