Abstract. The C2 domain of protein kinase C α (PKC α) corresponds to the regulatory sequence motif, found in a large variety of membrane trafficking and signal transduction proteins, that mediates the recruitment of proteins by phospholipid membranes. In the PKC α isoenzyme, the Ca²⁺-dependent binding to membranes is highly specific to 1,2-*sn*-phosphatidyl-L-serine. Intrinsic Ca²⁺ binding tends to be of low affinity and non-cooperative, while phospholipid membranes enhance the overall affinity of Ca²⁺ and convert it into cooperative binding. The crystal structure of a ternary complex of the PKC α -C2 domain showed the binding of two calcium ions and of one 1,2-dicaproyl-*sn*-phosphatidyl-L-serine (DCPS) molecule that was coordinated directly to one of the calcium ions. The structures of the C2 domain of PKC α crystallised in the presence of Ca²⁺ with either 1,2- diacetyl-*sn*-phosphatidyl-L-serine (DAPS) or 1,2-dicaproyl-*sn*-phosphatidic acid (DCPA) have now been determined and refined at 1.9 Å and at 2.0 Å, respectively. DAPS, a phospholipid with short hydrocarbon chains, was expected to facilitate the accommodation of the phospholipid ligand inside the Ca²⁺-binding pocket. DCPA, with a phosphatidic acid (PA) head group, was used to investigate the preference for phospholipids with phosphatidyl-L-serine (PS) head groups. The two structures determined show the presence of an additional binding site for anionic phospholipids in the vicinity of the conserved lysine-rich cluster. Site-directed mutagenesis, on the lysine residues from this cluster that interact directly with the phospholipid, revealed a substantial decrease in C2 domain binding to vesicles when concentrations of either PS or PA were increased in the absence of Ca²⁺. In the complex of the C2 domain with DAPS a third Ca²⁺, which binds an extra phosphate group, was identified in the calcium-binding regions (CBRs). The interplay between calcium ions and phosphate groups or phospholipid molecules in the C2 domain of PKC α is supported by the specificity and spatial organisation of the binding sites in the domain and by the variable occupancies of

ligands found in the different crystal structures. Implications for PKC α activity of these structural results, in particular at the level of the binding affinity of the C2 domain to membranes, are discussed.

Keywords: C2 domain; protein kinase C; phosphatidic acid; phosphatidylserine; X-ray structures

Abbreviations used: PK, protein kinase; DAG, diacylglycerol; DCPS, 1,2-dicaproyl-*sn*-phosphatidyl-L-serine; DAPS, 1,2-diacetyl-*sn*-phosphatidyl-L-serine; DCPA, 1,2-dicaproyl-*sn*-phosphatidic acid; PA, phosphatidic acid; PS, phosphatidyl-L-serine; CBR, calcium-binding region.

Introduction

Protein kinase C (PKC) is a family of phospholipid- dependent serine/threonine kinases that includes at least 11 different mammalian isoforms. PKCs can be classified into three groups, according to their structure and cofactor regulation: the first group includes the classical isoforms (α , β I, β II, and γ) that are activated by diacylglycerol (DAG) and cooperatively by calcium and acidic phospholipids. The second group consists of novel PKCs (δ , λ , η and ν), which are also activated by acidic phospholipids and DAG, though their function is not regulated by Ca^{2+} . The third group comprises the atypical PKC isoforms (ζ , λ and μ), whose regulation has not been clearly established, although their activity is stimulated by phosphatidylserine (PS). [1,2]

In conventional PKC isotypes, binding sites for their activators are located in the amino-terminal regulatory domain [3] composed of three functionally different elements: (i) a self-inhibiting pseudosubstrate sequence at the amino terminus, which, upon activation is thought to be released from the active site of the enzyme. (ii) The C1 domain that contains two cysteine-rich modules (C1A and C1B) and binds DAG and phorbol esters. (iii) The C2 domain, which is located at the carboxy end of the regulatory region and is responsible for binding to Ca^{2+} and to anionic phospholipids.

In the PKC α isoenzyme, the Ca²⁺-dependent binding to membranes is highly specific for 1,2-*sn*-phosphatidyl-L-serine. [4–7] Homologues of the PKC α C2 domain correspond to a regulatory sequence motif of about 130 amino acid residues that is found in a large variety of membrane trafficking and signal transduction proteins, in which the domain mediates the protein recruitment by phospholipid membranes. [8,9] All C2 domains are composed of a stable β -sandwich with flexible loops on top and at the bottom. The Ca²⁺-binding regions (CBRs), in the C2 domains that bind Ca²⁺, are formed mainly by five aspartate side-chains, located at the flexible top loops, that serve as bidentated ligands for two or three calcium ions.[10 – 15] Intrinsic Ca²⁺ binding tends to be of low affinity and non-cooperative, probably because the bound calcium ions contain empty coordination sites.[16,17] Phospholipid membranes increase overall Ca²⁺ affinity and convert Ca²⁺ binding into cooperative.[11,13,18 – 20] It is likely that phospholipids achieve this effect by providing additional coordination sites for the incompletely bound Ca²⁺. [21] The structure of the ternary complex of the PKC α -C2 domain with Ca²⁺ and 1,2-dicaproyl- *sn*-phosphatidyl-L-serine (DCPS) determined recently,[15] showed one of the Ca²⁺ coordinated simultaneously by the CBRs and by the head group of a DCPS molecule, which interacts also with some of the positively charged residues surrounding the calcium-binding pocket. Fatty acyl chains from the DCPS molecule, though partially exposed to the solvent, made hydrophobic contacts with residues from CBR3.

The crystal structures of the C2 domain of PKC α , crystallised in the presence of Ca²⁺ and of either 1,2-diacetyl-*sn*-phosphatidyl-L-serine (DAPS) or 1,2-dicaproyl-*sn*-phosphatidic acid (DCPA), are explained in this study. DAPS, a phospholipid with shorter hydrocarbon chains than DCPS, was chosen in order to facilitate the accommodation of the phospholipid inside the Ca²⁺-binding pocket. Comparisons between the ternary complexes with either DCPA or DCPS were expected to provide information on the specificity of PKC α for the PS head group.

Figure 1. Overall structures of the C2 domain of PKC α bound to (a) DAPS and (b) DCPA. β -Strands are depicted as arrows. The calcium ions located at the top of the domain, in the calcium-binding regions (CBRs), are represented as yellow balls. The phosphate group and phospholipid molecules are depicted as filled sticks. For the DCPA molecule found in the calcium-binding region, only the phosphoryl moiety was clearly defined (see the text). Coordination schemes of the calcium ions in the two structures are shown in the lower part of the Figure. The scheme of the DCPA complex assumes that only Ca1 and Ca2 are present, though the partial occupancy of Ca3 is possible, as discussed extensively in the text (see also Figure 2).

Results

Overall structure and calcium-binding sites

The PKC α -C2 domain produced as a recombinant fragment, including residues from His155 to Gly293, was crystallised in the presence of Ca $^{2+}$ and the short-chain phospholipids DAPS and DCPA. Diffraction data sets were measured at 100 K, using synchrotron radiation, to resolutions of 1.9 Å and 2.0 Å for the DAPS and DCPA crystal complexes, respectively (Table 1). Coordinates from the isolated

PKC α -C2 domain [15] were used as the searching model to determine the structure of the two complexes by molecular replacement (see Materials and Methods). In both crystals, the quality of the final electron density maps allowed the accurate positioning of most residues and side-chains. Only densities of the highly exposed *N*-terminal residues His155 to Lys158 and of side chains from Lys197 and Arg252 were poorly defined in both structures. The root-mean-square deviation (rmsd) of the superimposition of the 134 equivalent Ca atoms from the C2 domains in the crystal structures of the two complexes is 0.18 Å, which reflects the fact that these structures are essentially identical in conformation (Figure 1). The structures of the C2 domain in both complexes are also closely related to the conformations determined previously, for the isolated domain and when complexed with DCPS, [15] which gave rmsd values of only about 0.2 Å (Table 2).

The final model for the PKC α -C2–Ca²⁺–DAPS complex includes a C2 domain, 78 solvent molecules, three calcium ions and one phosphate ion, and two DAPS molecules (Table 1). Two of the calcium ions, equivalent to the central calcium sites II and III according to the convention of Essen *et al.*, [12] coincided with Ca1 and Ca2, as defined previously in the structures of the isolated PKC α -C2 domain and in the structure of the PKC α -C2–Ca²⁺–DCPS complex. [15] The third Ca²⁺ (indicated as Ca3 in Figures 1 and 2) was at a location equivalent to site IV, as defined by Essen *et al.*, [12] and had a strong peak of density in its vicinity that was interpreted as a phosphate ion, probably coming from the solution employed in crystallization (Figure 2). In the crystal structures of the isolated C2 domain and of its complex with DCPS, the site corresponding to Ca3 is occupied by one water molecule. [15] The first DAPS molecule was found inside the Ca²⁺-binding pocket connected to Ca1 in a location equivalent to that in the DCPS complex (Figure 1). [15] Density corresponding to this DAPS molecule was strong only for the phosphoserine moiety, having a maximum in the position of the phosphate group. Well-defined electron density for a second DAPS molecule was found near the conserved lysine-rich cluster, which includes lysine residues at positions 197, 199, 209, 211 and 213 from strands (β 3 and (β 4 (Figure 3).

Figure 2. Stereo-views of the PKC α C2 domain corresponding to site IV, [14] as found in the structures of the ternary complexes with (a) DCPS [15], (b) DAPS or (c) DCPA. Only protein residues that define the coordination sphere of Ca3 in the DAPS complex are depicted, though Asp248 has been omitted for clarity (see the coordination schemes in Figure 1) and the side-chain of Arg252, disordered in the three complexes, is not represented. Ca3 is represented as a green ball and water molecules in its vicinity in red. The phosphate ion coordinating with both Ca3 and Ca2 is shown in the DAPS complex $2F_o - F_c$ electron density maps (SigmaA weighted), contoured at 1.0 σ , are shown with a chicken-box representation for the (b) DAPS and (c) DCPA structures. Weakness of the electron density (c) in the DCPA complex corresponding to the location occupied by Ca3 in (b) the DAPS complex suggests the partial occupancy of calcium in this site in the DCPA structure (see the text and Table 2).

The final structure of the PKC α -C2- Ca²⁺-DCPA ternary complex includes a C2 domain, 50 solvent molecules, two or three (see below) calcium ions and two DCPA molecules (Table 1). In this complex, electron density confirmed the presence of the Ca²⁺ corresponding to Ca1 and Ca2, while density, in the location corresponding to Ca3 in the DAPS complex, was weak, which could be interpreted either as a Ca²⁺ with low occupancy ($B_{factor} = 59.2 \text{ \AA}^2$) or as a well-defined water molecule ($B_{factor} = 29.2 \text{ \AA}^2$; Figure 2). Also absent from the DCPA complex was density, equivalent to the density seen close to Ca3 in the DAPS complex, that could correspond to a phosphate molecule (Figure 2). The two DCPA molecules found in the DCPA complex were in the same locations as the two phospholipids in the DAPS complex: (i) at the Ca²⁺-binding site in the vicinity of Ca1; and (ii) near the conserved lysine-rich cluster (Figure 3). However, electron density for the DCPA molecule in the Ca²⁺ pocket, even poorer than for the corresponding molecule in the DAPS complex, was well defined only for the phosphoryl moiety, weakening fast for the glycerol and acyl chains. Electron density for the second DCPA molecule near the lysine-rich cluster was clear for the phosphoryl and glycerol head groups, and for the first carbon atoms of the acyl chains (Figure 3). Ca1 and Ca2, in both the DAPS and the DCPA complexes, were heptacoordinated, while Ca3, in the DAPS complex, was hexacoordinated (Figure 1). In all cases, the Ca²⁺-ligand coordination distances ran from 2.3 to 2.6 Å. Protein Ca²⁺ ligands corresponded to the side-chains of the five conserved aspartic residues (at positions 187, 193, 246, 248 and 254) and to the main chain of residues Met186 and Trp247, which provided six of the seven oxygen atoms that coordinate Ca1 and Ca2, as found in the PKC α -C2-DCPS structure.[15] The seventh ligand of Ca1 was an oxygen atom

from the phosphoryl group of either the DAPS or DCPA molecule in the DAPS or DCPA complexes, respectively. Four of the six Ca3 ligands were protein oxygen atoms from the main chain of Arg252 and from the side-chains of Asp248, Thr251 and Asp254 (Figure 2). The fifth and sixth ligands of Ca3 were, respectively, a water molecule and the extra phosphate ion, which interacted also with Ca2 (Figure 1).

Table 2. Summary of calcium ions and phosphate and phospholipid molecules found in the four PKC α -C2 domain.

PKC α -C2 domain structures	Ca ²⁺	Ca ²⁺ -DCPS ^a	Ca ²⁺ -DCPA ^b	Ca ²⁺ -DAPS ^b
Number Ca ²⁺	2	2 ^c	2 ^d	3
Ligands in the calcium-binding region	Ca1-PO ₄ , Ca2-H ₂ O	Ca1-DCPS (0.5 occupancy), Ca2-H ₂ O	Ca1-DCPA ^e , Ca2-H ₂ O	DAPS ^f , Ca2-PO ₄ - Ca3
Ligands in the lysine-rich cluster region	PO ₄ (poor)	PO ₄ (poor)	DCPA (acyl chains are only visible in part)	DAPS (whole molecule)

^c One water molecule could be another Ca²⁺ with very low occupancy

^d One water molecule is likely to be another Ca²⁺ with low occupancy

^e Only the phosphoryl group from this DCPA molecule is well defined with an assigned occupancy of 1.0 (see the text)

^f Both the phosphoryl and the seryl groups from this DAPS molecule are well defined with assigned occupancies of 1.0 (see the text)

Figure 3. Stereo-views of the PKCα C2 domain corresponding to the lysine-rich cluster regions as found in the structures of the ternary complexes with (a) DCPS,15 (b) DAPS or (c) DCPA. $2F_o - F_c$ (SigmaA weighted) electron density maps, contoured at 1.0σ , are shown with a chicken-box representation for the (b) DAPS and (c) DCPA structures. For clarity, only residues directly involved in the interaction with the phospholipids in the DCPS complex are shown (see Figure 4). Phosphate and phospholipid ligands are represented with the thickest sticks.

Figure 4. Plot of interactions, drawn with the LIGPLOT program, [41] between the PKC α -C2 domain with (a) the DAPS and (b) the DCPA molecules found in the lysine-rich cluster in the corresponding structures (see the text and Figure 3).

Interactions of DAPS and DCPA

The phosphoglycerol backbone of the phospholipid pocket had similar interactions in the DAPS and the DCPA complexes. One of the phosphoryl oxygen atoms from the phospholipid was coordinated with Ca1, while the glycerol moiety was hydrogen-bonded to the guanidinium groups of arginine residues 216 and 249. In the DAPS complex, the phospholipid serine head group interacted also with the C2 domain residues Pro188 and Asn189 in CBR1. These specific interactions between the serine residue from the phospholipid and the C2 domain, necessarily absent from the DCPA complex, could contribute to the enhanced affinity of PKC α for PS-containing membranes. Interactions equivalent to those

described for the DAPS complex were found in the structure of the PKC α -C2 domain with DCPS. [15] However, in the DCPS complex, the fatty acyl chains from the phospholipid had hydrophobic contacts with residues from CBR3. These interactions, which might contribute to binding, were not present in the DAPS complex, because of the short hydrocarbon chains of DAPS.

A second phospholipid ligand was found, as indicated before, near the conserved lysine-rich cluster in both the DAPS and the DCPA complexes (Figures 3 and 4). The clustering of the exposed lysine side-chains, from the β 3 and β 4 strands, endowed the concave surface of the C2 domain with a strong positive electrostatic character suited to interact with anionic charges. The head group from the DAPS molecule found near the lysine-rich cluster had a conformation more extended than that in the two PS lipid molecules, DAPS and DCPS, found in the calcium-binding pocket. [15] The DAPS terminal carboxylate group, from the serine moiety, made a short and strong salt-bridge with Lys209 (Figures 3 and 4). The Lys197 side-chain, though not well defined, pointed towards the carboxylate group, probably also interacting ionically. Finally, the carboxylate group interacted with a well-defined water molecule that is bound to Lys199 (Figures 3 and 4). In turn, the DAPS phosphate group had an ionic interaction with the side-chain of Lys211 and made a hydrogen bond with the phenol oxygen atom of Tyr195 (Figures 3 and 4). The C2 domain residues Trp245 and Asn253 contacted the DAPS glycerol and acyl chains (Figures 3 and 4). The short fatty acyl chains of the DAPS molecule appear to point towards the solvent (Figure 5), which could explain the difficulties in filling this site with a phospholipid with longer acyl chains, such as DCPS. [15] However, DCPA, despite having fatty acyl chains the same length as DCPS, is able to bind near the lysine-rich cluster and the polar head of a DCPA molecule was clearly defined at this site in the DCPA complex (Figure 3). Fatty acyl chains of this DCPA molecule departed from the surface of the C2 domain, becoming fully exposed to the solvent and disordered except for the first few (one to three) carbon atoms (Figures 3 and 4). The phosphoryl group of this DCPA molecule was located in the position occupied by the terminal carboxylate group in the DAPS complex and had almost identical interactions: (i) a strong salt-bridge with Lys209; (ii) a hydrogen bond with a well-defined water molecule that, in turn, is bound to the side chain of Lys199; and (iii) a second probable salt bridge with Lys197, which was oriented towards the phosphoryl group but was partially disordered, as was the case in the DAPS complex (Figures 3 and 4). C2 domain residues Tyr195, Lys211 and Asn253 had a number of different interactions with the DCPA molecule (Figure 4).

The proximity, both in sequence and in the spatial organisation, of the residues defining the Ca3 binding site (particularly Asp248, Thr251 and the main chain of Arg252) to some of the residues from the lysine-rich cluster region interacting with the phospholipids, particularly Asn253, should be noted (Figure 1).

Figure 5. Stereo-view of the packing interactions in the vicinity of the two phospholipid-binding sites found in the structure of the ternary complex PKC α -C2–Ca²⁺–DAPS. The reference molecule is depicted in green and the phospholipid ligands in atom colour code. The three closest neighbour molecules are presented in grey.

Site-directed mutagenesis analysis

The structures of the PKC α -C2 domain with DAPS and DCPA determined in the present study prompted us to re-investigate the lysine-rich cluster by site-directed mutagenesis. Two constructs were engineered fused to glutathione-S-transferase (GST): (i) in the first construct, wild-type lysine residues 209 and 211 were replaced by alanine (GST-C2 α -K209A/K211A); and (ii) in the second construct, lysine residue 197 was changed to alanine (GST-C2 α -K197A/K209A/K211A). Binding assays to vesicles with increasing percentages of either PS or PA were performed for both constructs in the presence of 200 mM CaCl₂ and in the absence of calcium (Figure 6).

When calcium was present, the maximal binding activity and the affinity of the two constructs had almost the same behaviour as that of the wildtype protein (Figure 6(a) and (c)). Instead, when calcium was absent, important differences were observed (Figure 6(b) and (d)). For vesicles containing PS, the maximal binding activity of the two constructs reached only about 30% with respect to the wild-type protein. For vesicles containing PA, the maximal binding activity of the constructs was about 50% compared to that of the wild-type protein. Note also that in the absence of calcium the affinity of the wild-type protein to bind to PA-containing vesicles is higher than that exhibited for PS-containing vesicles (Figure 6(a) and (c)).

Figure 6. PS dependence of phospholipid binding to the GST-C2 α domain (X), GST-C2 α -K209A/K211A (W) and GST-C2 α -K197A/ K209A/K211A (P) (a) in the presence of 200 mM CaCl₂ and (b) in its absence. Binding of ³H-labelled PC/PS small unilamellar vesicles to the different constructs was analysed by increasing the concentration of PS in the vesicles. Similar studies were made of the PA dependence of phospholipid binding to the GST-C2 α domain (X), GSTC2 α -K209A/K211A (W) and GSTC2 α - K197A/K209A/K211A (P) (c) in the presence of 200 mM CaCl₂ and (d) in its absence. For PA, the binding of ³H-labeled PC/PA small unilamellar vesicles to the different constructs was analysed by increasing the concentration of PA in the vesicles. In all cases, GST was used as a background control, with error bars indicating the standard error for triplicate determinations.

Discussion

The present study was initiated to complement the information obtained with the crystal structures of the isolated C2 domain of PKC α and of the ternary complex of the domain with Ca²⁺ and DCPS. [15] The structure of the ternary complex showed, bound to the protein, two calcium ions, one phosphate group in the lysine-rich cluster region, and one DCPS molecule in the calcium-binding pocket with only 50% occupancy (Table 2). The direct coordination of Ca1 with the head group of the bound DCPS molecule provided an apparently straightforward explanation of the relationships between the two ligands. In addition, specific interactions of the serine moiety of the phospholipid explained, at least in part, the preference of PKC α for phosphatidyl-L-serine lipids. Mutational analysis confirmed that some residues, seen in direct contact with the DCPS molecule, play a critical role in PS-dependent activation and membrane translocation of PKC α . [22,23] Furthermore, hydrophobic contacts between the DCPS fatty acyl chains and residues from CBR3 suggested the penetration of this region inside the anionic membranes, which confirmed a number of previous observations. [24,25] However, despite these hydrophobic contacts, solvent accessibility and positional disorder increased along the fatty acyl chains, which might interfere with complex formation and crystal packing leading to the low occupancy of the bound phospholipid found in the ternary complex with DCPS (Figure 5). [15] Therefore, it was hypothesized that a PS lipid with shorter hydrocarbon chains than DCPS, such as DAPS, might facilitate the accommodation of the phospholipid inside the calcium-binding pocket, increasing occupancy and

improving the definition. Differences between complexes of the C2 domain and different phospholipids with and without the serine group, such as DCPS and DCPA, were expected to provide clues to the preference of PKC α for PS-containing membranes.

Confirming expectations, the DAPS molecule found inside the calcium-binding pocket, that corresponds well in location and interactions to the only DCPS molecule found in the DCPS complex, had higher occupancy in the DAPS complex (Table 2). In the DCPA complex, the absence of the serine headgroup and of its specific interactions seems to reduce, as anticipated, the affinity for the binding site inside the calcium pocket and only the phosphoryl moiety from the DCPA molecule appears well defined.

Despite the findings, described above, that confirmed the initial hypothesis, the results obtained from the crystal structures of DAPS or DCPA had important novel features. Both the DAPS and the DCPA complexes showed clearly a second molecule of phospholipid bound at a new site of the C2 domain. The additional binding site was located not inside the calcium-binding pocket but in the vicinity of the conserved lysine-rich cluster in the concave surface of the C2 domain (Figures 1 and 3). In the complex with DAPS, a third Ca²⁺ was present, coordinated with an extra phosphate group, in the top region of the C2 domain (Figures 1 and 2). In the complex with DCPA, the third Ca²⁺ might be present with partial occupancy (Figure 2).

Calcium-binding site. The third calcium ion

Why is the third calcium ion absent from the DCPS complex and possible present, but only with partial occupancy, in the DCPA complex? The binding of the third calcium ion seems to correlate with the presence of phospholipids in the lysine-rich site. The interplay between both ligands is suggested also by the spatial proximity of the two binding sites (Figure 1). However, as no significant structural rearrangement of the C2 domain was detected between the DAPS, DCPS and DCPA complexes, no important cooperative effects are expected due to the binding in the lysine-rich cluster site. [26] The high occupancy of the third calcium ion in the DAPS complex besides the presence of the phospholipid in the lysine-rich cluster site could reflect some contribution from PS bound in the calcium pocket. The presence of the phosphate group interacting with Ca3 indicates that a third binding site for head groups of anionic phospholipids could be available in the C2 domain when the third calcium ion is bound. The direct involvement of the side-chain from residue Thr251 in the coordination of the third calcium ion could contribute to the dramatic effects observed by mutational analysis on this residue [23] that was reported to interact also with the phospholipid in the DCPS complex. [15] In any event, the third calcium ion is likely to bind with extremely low affinity in solution but might become trapped physiologically in a ternary C2 domain–membrane complex similar to what has been proposed to happen in PKC β . [27]

The lysine-rich cluster binding site

Possible functions of the conserved and characteristic lysine-rich cluster from the C2 domain of classical PKCs had been investigated, in particular by mutational analysis, with no clear consequences for enzymatic activity. [23,28 – 30] However, in the crystal structure of the PKC α -C2 domain with DCPS,

one phosphate group was identified in the lysine-rich cluster region. [15] When co-crystallised with *O*-phospho-L-serine, the structure of the C2 domain of PKC β , which contains a lysine-rich cluster in the molecular region equivalent to that in the PKC α -C2 domain, showed extra electron density near the cluster that was interpreted as corresponding to the *O*-phospho-L-serine ligand. [14] The site-directed mutagenesis studies presented in this work indicate that replacements of some residues from the lysine-rich cluster introduce, in fact, significant membrane-binding differences in the modified proteins with respect to the wild-type, but only in the absence of calcium (Figure 6). Hence, membrane binding by the C2 domain is dominated by the presence of calcium, though the lysine-rich cluster appears to have a minor, calcium-independent, contribution that becomes clearly detectable only when calcium is absent.

Phospholipid binding at the lysine-rich cluster appears to be dominated by electrostatic interactions, while hydrophobic contacts, likely to be required for membrane penetration, are mostly excluded. This electrostatic character suggests that anionic membranes should interact avidly with the lysine-rich cluster. Why then does the lysine-rich cluster have only a minor contribution in the binding of the isolated C2 domain to anionic membranes? Despite being at the surface of the protein, the lysine-rich cluster appears somehow inaccessible to interactions with the membrane. A simple explanation of this reduced accessibility is provided by the concave shape of the C2 domain. For the lysine-rich cluster to reach the surface of a membrane, some other parts of the C2 domain have to be in contact with the membrane. These other regions are limited to the CBR3 and to the calcium-binding pocket in the docking models, requiring minimal penetration of the C2 domain into the membrane. [15] Therefore, in the absence of calcium, the attractive interaction towards anionic membranes of the lysine-rich cluster is expected to be counterbalanced by the repulsive interactions of other parts of the protein, particularly by the negatively charged residues from the calcium binding pocket. In the presence of calcium, the behaviour is reversed, and binding to membranes would be dominated by the interactions mediated by the calcium ions. However, even in the presence of calcium, the lysine-rich cluster would contribute to determination of the positioning of the enzyme with respect to the membrane and to an increase in the stability of the protein-membrane docking to the levels required by the functioning of the enzyme at different stages.

Some of the structural features of the C2 domain can show its full meaning only in the context of the different conformations that the several parts of a PKC α molecule can adopt. Residue Asp55 from the C1A domain has been shown to be dramatically important for the activation of PKC α and those authors suggested this residue to be involved in the tethering of the C1A domain to another part of PKC α that keeps it in an inactive conformation at the resting state. [31] Modelling supports the attractive possibility of docking the C1A domain into the concave face of the C2 domain by placing the Asp55 side-chain near the lysine-rich cluster, while the hydrophobic surfaces corresponding to the DAG binding site, in the C1A domain, and to the CBR3 region, in the C2 domain, contact with each other (Figure 7). These interdomain interactions would explain the inaccessibility of the DAG binding site in the C1A domain [32] and possibly of the lysine-rich cluster site in the C2 domain, while maintaining the conformation of PKC α in the resting state. Calcium, when present, would trigger the binding of the C2 domain onto the anionic membranes leading to penetration of CBR3 into the membrane, [15] which would be facilitated by the removal of the C1A domain if bound to the concave surface of the C2 domain (see below).

Separation of domains C1A and C2 would, in turn, allow the DAG binding pocket and the lysine-rich cluster to become accessible and to experience further interactions. Work with the full-length PKC α to test these possibilities is being started.

Figure 7. Two views, 90° apart from each other, of the surface representation of electrostatic potentials in the isolated (a) C1A and (b) C2 domains. [42] Analysis on residue Asp55, from the C1A domain, [31] and on residues from the lysine-rich cluster suggests that both domains are interacting with other parts of PKC α in the inactive conformation at the resting state (see the text). (c) Modelling allows us to place the C1A domain into the convex surface of C2, with Asp55 interacting with the lysine-rich cluster and the C1A surface that includes the putative DAG binding pocket making mainly hydrophobic contacts with CBR3. The DAG binding pocket and the lysine-rich cluster would both become accessible to further interactions only after the separation of the C1A and C2 domain during the docking onto anionic membranes triggered by binding of calcium to the C2 domain (see the text).

Figure 8. Docking of the complex of the PKCa-C2 domain with three calcium ions onto a model membrane. The phosphate and the head groups from the two DAPS molecules found in the structure of the DAPS complex are shown to emphasise that they could correspond to three polar heads on the surface of anionic membranes. In the resulting docked model, only the central part of CBR3 from the C2 domain is inserted into the lipid bilayer, as had been proposed from the structure of the DCPS complex. [15]

Docking model

The Ca1 ion directly coordinated to the phosphoryl moiety of DCPS and a phosphate group in the lysine-rich cluster region in the DCPS complex suggested a binding mechanism of the C2 domain to phospholipid membranes. [15] According to this mechanism, the presence of Ca1, and of Ca2, would trigger the interaction with negatively charged phospholipids at the membrane surface. This first contact would enable different protein residues located in CBR3 to interact by penetrating into the membrane. The location of the phosphate ion, at the lysine-rich cluster region, could correspond to the polar head of another phospholipid molecule interacting electrostatically with the C2 domain. [15]

The results obtained in the present study seem to confirm most of the prominent peculiarities of the proposed docking mechanism and provide deeper understanding of some critical features, in particular: (i) the explicit demonstration of a second phospholipid-binding site in the vicinity of the lysine-rich cluster region where electrostatic interactions appear to act as the dominant binding forces and that would take place upon CBR3 membrane penetration. (ii) The possible correlation between the type and the occupancy of the lipids bound to the C2 domain and the occupancy and stability of the third calcium ion. (iii) The possibility of a third binding site for head groups of anionic phospholipids when a third calcium ion is bound. The three phospholipid-binding sites define a structurally feasible anchorage plane on the C2 domain (Figure 8).

Conclusions

C2 domains are remarkable modules present in a wide variety of proteins, in particular related to membrane trafficking and signal transduction. The C2 domain of PKC α is responsible for the initial Ca²⁺ and PS-dependent electrostatic binding of PKC α to anionic membranes. [22,24,29,32] The four crystallographic structures of the PKC α -C2 domain now available (Table 2) confirm that the number of calcium ions as well as the number of phosphate groups and phospholipid molecules bound to the domain can vary. The interplay between calcium ions and phosphate groups or phospholipid molecules in the C2 domain of PKC α is strongly supported by the specificity and spatial organization of the binding sites in the domain and by the variable occupancies of ligands found in the different crystal structures. These structural results, together with the wealth of biochemical and biological information available for PKCs allow us to envision an exquisite and versatile tuning of PKC α activity at the level of the binding affinity of the C2 domain to membranes.

Materials and Methods

Expression and purification of the PKC-C2 domain

The PKC α -C2 domain, including rat PKC α residues from His155 to Gly293, was expressed and purified as described [15] Expression and purification of the wild-type and mutants GST-PKC α -C2 domain was as described. [33] All the mutants were expressed as soluble proteins in *Escherichia coli* at levels comparable to that of the wild-type protein, which is an indication that none of the mutations produced severe conformational changes. Furthermore, residues changed in the lysine-rich cluster are exposed to the solvent with no apparent structure stabilizing roles.

Phospholipid binding measurement

Lipid vesicles were generated by mixing chloroform solutions of 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphocholine (POPC), 1-palmitoyl-2-oleoyl-*sn*-glycero-3-phosphoserine (POPS) or 1-palmitoyl-2-oleoyl-*sn*-phosphatidic acid (POPA) (Avanti Polar Lipids, Inc.) at the desired composition and dried from the organic solvent under a stream of nitrogen and then further dried under vacuum for 60 minutes. 1,2-Dipalmitoyl-L-3-phosphatidyl *N*-methyl-[³H]choline (Dupont; specific activity 56 Ci/mmol) was included in the lipid mixture as a tracer, at approximately 3000–6000 cpm/mg of phospholipid. Dried phospholipids were resuspended in 50 mM Hepes (pH 7.2), 0.1 M NaCl, 0.5 mM EGTA by vigorous vortex mixing and subjected to direct probe sonication (three cycles of 30 seconds). The suspension was centrifuged for 20 minutes at 14,000g to remove aggregated material. A standard assay [34] contained 20 mg of PKC-C2 domain bound to glutathione-Sepharose beads, which were prewashed with the respective test solutions and resuspended in 0.1 ml of 50 mM Hepes (pH 7.2), 0.1 M NaCl, 0.5 mM EGTA containing 20 mg of the corresponding lipids. The mixture was incubated at room temperature for 15 minutes with vigorous shaking, then centrifuged briefly in a tabletop centrifuge. The beads were washed three times with 1 ml of the incubation buffer without liposomes. Liposome binding was then quantified by liquid scintillation counting of the radioactivity associated with the beads.

Phospholipids used in the crystallographic analysis

1,2-Dicaproyl-*sn*-phosphatidic acid (DCPA) is a commercial product and was obtained from Avanti Polar Lipids, Inc. (Alabaster, AL).

1,2-Diacetyl-*sn*-phosphatidylserine (DAPS) was obtained as follows: L- α glycerophosphate di(monocyclohexylammonium) salt (Sigma) (1 g, 2.7 mmol) was dissolved in water and the solution was passed through a Dowex 50W x 4 (pyridinium form) column (6 cm x 3 cm) eluted with water (100 ml) to obtain glycerophosphate pyridinium salt. The elution was concentrated to dryness, yielding 0.65 g of an oily residue that was dried by evaporation of methanol and ethyl ether in a vacuum drier. The result was dissolved in 2.3 ml of acetic anhydride. Then a drop of concentrated sulphuric acid was added and the resulting mixture was heated at 50 °C for one hour. The mixture was cooled to room temperature and 10 ml of a water-ice mixture was added. The resulting mixture was kept at 4 °C overnight. An oil formed, which was separated from the water and dried under vacuum, yielding 0.8 g of the 1,2-diacetyl-*sn*-glycerophosphate as a white foam. This compound was dissolved in 20 ml of dry pyridine; and 0.43 g of t-butyloxycarbonyl (Boc)-L-serine and 2.1 g of *N,N*-dicyclohexylcarbodiimide was added. After 16 hours of stirring at room temperature, the solution was filtered to eliminate the dicyclohexylurea formed and the solution was concentrated to dryness. The residue was dissolved in water and washed with ethyl ether (three times) and dichloromethane (twice). The aqueous phase was concentrated to dryness. The residue was cooled with ice and dissolved in 5 ml of trifluoroacetic acid (TFA). The solution was kept at room temperature for 20 minutes and 20 ml of ethyl ether was added. A yellowish oil formed that was recovered by centrifugation, yielding 0.4 g of the desired product carrying pyridinium as a counter ion. Before use of this compound for crystallisation, aliquots of the product were passed over a Dowex 50W x 4 (sodium form) eluted with water to obtain the sodium salt. ^1H NMR δ (CD_3OD) ppm: 4.2 (m, 1H), 4.08 (m, 1H), 3.92 (m, 2H), 3.62 (m, 2H), 1.97 (s, 3H), 1.89 (s, 3H). EM (electrospray, negative mode): 342.92 ($\text{M} - \text{H}^+$), 112.7 ($\text{TFA} - \text{H}^+$) expected for $\text{C}_{10}\text{H}_{18}\text{O}_{10}\text{NP}$ 344.18.

Crystallisation and data collection

Solutions containing the PKC α -C2 domain at 8 mg/ml were pre-incubated overnight at 4 °C with 25 mM CaCl_2 and 2 mM of DCPA and DAPS, respectively. Crystals of both complexes were obtained with the hanging-drop, vapour-diffusion technique at 20 °C by mixing 1 μl of the protein complex with an equal volume of the crystallization buffer that contained 20% (w/v) polyethylene glycol (PEG8K) and 50 mM potassium phosphate (pH 6.5), inverted over a 1 ml reservoir containing the crystallization buffer. Crystals from both the PKC α -C2- Ca^{2+} -DAPS and PKC α -C2- Ca^{2+} -DCPA complexes appeared in three to four days and grew, for three weeks, up to 0.6 mm x 0.1 mm x 0.1 mm in size. Crystals from the two complexes were isomorphous, space group $P3_221$, and contained one protein subunit per asymmetric unit with a solvent volume content of about 50% (v/v). Diffraction data sets were collected at 100 K on a MarCCD detector using synchrotron radiation at the ESRF (Grenoble), at 1.9 Å and 2.0 Å resolution for the DAPS and DCPA crystal complexes, respectively. Crystals were cryo-protected by soaking for one

minute in a solution containing the crystallisation buffer and 20% (v/v) glycerol. Diffraction intensities were evaluated and scaled internally using the MOSFLM [35] and SCALA [36] programs from the CCP4 package (Table 1).

Structure determination and refinement

For crystals of the PKC α -C2- Ca²⁺-DAPS and the PKC α -C2- Ca²⁺-DCPA complexes, the coordinates of the PKC α -C2- Ca²⁺ model (PDB ID code 1DSY), [15] with solvent molecules and ions omitted, were used as the starting model to determine the structure of the two complexes by molecular replacement using the AMoRe program. [37] Final models of the two complexes were obtained by iterative cycles of manual rebuilding with program O [38] and automatic refinement with CNS, [39] including bulk solvent correction and restrained isotropic individual *B*-factors at the final rounds of refinement. Both structures exhibit good stereochemistry, with all the residues situated inside the most favourable or the permitted regions of the Ramachandran plots (Table 1). [40] Difference and omit ($2F_o - F_c$) and ($F_o - F_c$) electron density maps for the DAPS complex indicated the presence of three calcium ions at the top of the b-sandwich at the putative Ca²⁺-binding site. Two of the calcium ions coincided with Ca1 and Ca2, as defined in the structure of the PKC α - Ca²⁺-DCPS complex, [15] while the third was found in a location equivalent to site IV, as defined in the structure of PKC β -C2. [14] Electron density indicated the presence of a DAPS molecule in close contact with Ca1 and of a phosphate ion in the vicinity of Ca3. Finally, well-defined electron density near the lysine-rich cluster from strands (β 3 and β 4) was interpreted as a second DAPS molecule. In the DCPA complex, electron density confirmed the presence of calcium ions Ca1 and Ca2, but was weaker at the location for Ca3, which could be interpreted either as a well-defined water molecule or as a Ca²⁺ with low occupancy. Non-protein electron density in the vicinity of Ca1 was assigned to a DAPS molecule, though only the region for the phosphate group was well defined. Finally, electron density near the lysine-rich cluster, again clearly visible in the DCPA complex, was interpreted as corresponding to the phosphoryl and glycerol head groups of the phospholipid molecule.

Deposition of coordinates

Coordinates of the ternary complexes of PKC α - Ca²⁺ with both DAPS and DCPA, reported in this study, will be deposited in the Protein Data Bank and are available directly from the authors on request until they are processed and released.

Acknowledgments

This research was supported by grants PB98-0389 to the Universidad de Murcia, and BIO099-0865 to the IBMB and by 1FD97-1558 from DGESIC (Spain) to a collaborative project between the Universidad de Murcia and the IBMB. Data were collected at the EMBL protein crystallography beam lines at ESRF (Grenoble) within a Block Allocation Group (BAG Barcelona), as at ESRF BM14. This

work was supported financially by the ESRF and by grant HPRI-CT-1999-00022 of the European Union. We specially thank the ESRF local contacts and the team of the Spanish CRG beam line BM14 for providing assistance and support for measurements.
