PURPOSE. We estimated the contribution of the gradient refractive index (GRIN) and lens surfaces to lens astigmatism and lens astigmatic angle as a function of age in human donor lenses.

METHODS. Human lenses were imaged, ex vivo, with 3D-spectral optical coherence tomography (OCT) and their back focal length was measured using laser ray tracing. The contribution of lens surfaces and GRIN to lens astigmatism were evaluated by computational ray tracing on the GRIN lens and a homogenous equivalent index lens. Astigmatism magnitude and relative astigmatic angle of and between lens surfaces, GRIN lens, and lens with homogeneous refractive index were evaluated, and all results were correlated with age.

RESULTS. The magnitude of astigmatism in the anterior lens surface decreased with age (slope = -0.005 diopters [D]/y; $r = 0.397$, $P = 0.018$). Posterior surface astigmatism and lens astigmatism were not age-dependent. Presence of GRIN did not alter significantly the magnitude or axis of the lens astigmatism. The astigmatism of GRIN lens and lens with homogeneous refractive index correlated with anterior lens surface astigmatism (GRIN, $P = 3.9E - 6$, $r = 0.693$; equivalent refractive index lens, $P = 4.1E - 4$, $r = 0.565$). The astigmatic angle of posterior surface, GRIN lens, and homogeneous refractive index lens did not change significantly with age.

CONCLUSIONS. The axis of lens astigmatism is close to the astigmatic axis of the anterior lens surface. Age-related changes in lens astigmatism appear to be related to changes in the anterior lens astigmatism. The influence of the GRIN on lens astigmatism and the astigmatic axis is minor.

Keywords: crystalline lens, GRIN, astigmatism

The human crystalline lens is an optical element that, together with the cornea, refracts and transmits the light to form an image on the retina. Its optical properties are dependent on its shape and its index of refraction, which is not homogeneous, and is known to peak in the center of the lens and decrease toward the cortex in all directions. The gradient refractive index (GRIN)^{1–6} and lens shape^{7–11} change with age, resulting in an age-dependency of the optical properties of the lens and, therefore, the whole eye. It has been shown that the lens spherical aberration shifts toward more positive values with age.^{9,10,12–14} Measurements of total and corneal spherical aberrations have shown that the crystalline lens is primarily responsible for age-related loss of corneal/internal balance of spherical aberration.^{14–16}

Several studies have reported changes in the geometrical shape of the lens with age, such as lens thickening and lens surface steepening.^{1,8,11,12,17–19} Since the eye does not tend to become myopic with age, it was postulated that the lens GRIN changed in such a way that it compensated for lens surface steepening to maintain lens power constant with age (so-called lens paradox).^{1,11,20}

Direct measurements of the GRIN distribution in the lens and its change with age are scarce. Earlier studies used a reflectometric fiberoptic sensor,²¹ or magnetic resonance imaging.^{22,23} More recently, a technique based on optical coherence tomography (OCT) has been proposed,⁵ which has

allowed estimates of the GRIN distribution ex vivo in two-dimension (2D) in human donor lenses as a function of age,²⁴ and cynomolgus monkey lenses as a function of accommodation,²⁵ and in three-dimensional (3D) ex vivo in porcine lenses and human lenses of different ages.^{6,26} In humans, it has been found that, with age, the GRIN profile changes from a parabolic shape to a central plateau with constant index and a rapid decrease toward the periphery,^{1,22,24} more prominent in the meridional than in the axial direction.²⁶ Ray tracing estimates of the spherical aberration in ex vivo human lenses using the measured geometrical shape and the estimated GRIN revealed a significant contribution of the GRIN in the negative spherical aberration of young lenses,²⁷ as well as a shift of the spherical aberration toward less negative values with aging.²⁶ There was an excellent agreement between the estimated spherical aberration and that measured by laser ray tracing (LRT) in the same lenses.²⁸ Previous studies^{29,30} also evaluated the impact of the GRIN, as opposed to the assumed constant index, in the quantification of the posterior lens shape from OCT imaging.

While the contributions of the cornea and lens, as well as the lens shape and GRIN to spherical aberration have been relatively well studied, to our knowledge a similar analysis has not been performed on the relative contributions to astigmatism, likely because most lens studies to date only had access to 2D data.

Compensatory effects of anterior and posterior corneal astigmatism have been reported.^{31–37} Also, longitudinal studies report changes in the cornea from with-the-rule (direct) to against-the-rule (indirect) astigmatism with age.³⁸ Measurements of total and corneal astigmatism from ocular refraction^{39,40} or ocular aberration measurements^{15,41} suggest at least partial compensation of total and internal astigmatism. In those studies, the contributions of the posterior cornea and lens to the internal optics cannot be isolated. In an interesting study using an ophthalmophakometric technique, Elawad et al.⁴² estimated the ocular component contributions to residual astigmatism in human eyes, and found that, while the astigmatic contributions of the posterior corneal and lens surfaces were predominantly inverse, direct astigmatism came from the anterior lens surface. Similar conclusions were reached by Dunne et al.⁴³ in a later work, although they recognized that the method was indirect and prone to accumulated experimental errors.

Lens surface astigmatism was studied in human cadaver lenses using a corneal topography system.⁴⁴ In this study, radius of curvature and shape factor were fitted over 18 meridians. In most cases the variations were random, but in some cases the variations indicated the presence of regular lens astigmatism.

To our knowledge, the only direct measurement of crystalline lens surface astigmatism on ex vivo human lenses comes from surface topographic analysis (using OCT).⁴⁵ In that study it was found that astigmatism was the predominant lens surface aberration. A significant change in the amount of surface astigmatism aberration with age was not found, although the relative angle of astigmatism between the anterior and posterior lens surfaces tended to decrease with age, indicating a potential decrease in the compensatory effects of anterior and posterior lens astigmatism with age. The study did not consider potential effects of the GRIN distribution with age.

Access to lens shape and GRIN in 3D opens the possibility of evaluating the relative role of lens surfaces and GRIN astigmatism to lens astigmatism, and the potential changes with age, as in similar analysis of contributors of spherical aberration.

For this study, we used 3D spectral OCT data on 35 isolated human lenses (47.6 ± 13.4 years), of which shape and GRIN had been characterized in 3D.²⁶ We present here lens surface astigmatism, and lens astigmatism, and their changes in magnitude and axis with age. In particular, the contribution of surface and GRIN astigmatism to the lens astigmatism was studied assuming an equivalent refractive index, and the estimated GRIN.

It is particularly interesting to understand the contribution of the different lens surfaces to the optical quality of the eye in the context of potential replacements of the presbyopic or cataractous crystalline lens. This contribution seems especially relevant for the management of astigmatism with toric intraocular lenses, since it explains the contribution of the eventually replaced crystalline lens to the astigmatism of the eye.

METHODS

Human Lens Samples and Preparation

All human donor eyes were received from the Transplant Service Foundation (TSF) Eye Bank in Barcelona, Spain. During the transportation, eyes were packed individually in sealed vials at 4°C, wrapped in gauze soaked in a preservation medium (Dulbecco's modified Eagle's medium [DMEM]/F-12, HEPES, no phenol red; GIBCO, Carlsbad, CA, USA). Presence of

any form of cataract was considered an exclusion criterion for the study. Before shipment the corneas had been removed (for corneal transplant purposes) and in some cases sections of the sclera. However, the vitreous and the choroid were preserved and provided a safe transportation environment for the lens. All lenses arrived 1 to 2 days post mortem, and were measured within 24 hours.

A total of 35 eyes from 30 human donors were used in the study. Ages ranged between 19 and 71 years. Before the experiment, the lens zonules were carefully cut and the lens was extracted from the eye with soft tweezers and handled mainly using the remaining zonules rather than touching the lens capsule. After extraction the lens was immediately immersed in DMEM at room temperature. During the measurements, the lens was placed on a ring in a DMEM-filled cuvette. The whole measurement took up to 2 hours. Swollen or damaged lenses were identified with the OCT images and excluded from the study.

Handling and experimental protocols had been approved previously by the Institutional Review Boards of TSF and CSIC. Methods for securing human tissue were in compliance with the Declaration of Helsinki.

OCT Imaging

The cuvette containing the lens was placed on a horizontal platform, and imaged using a custom developed high resolution spectral OCT system described in detail elsewhere.⁴⁶ A mirror system above the platform assured that the OCT beam was directed toward the upper lens surface. The system uses an 840-nm superluminescent (SLD) diode as illumination source and obtained 3D images composed of 1668 A-Scans, and 70 B-Scans on a 12×12 -mm lateral area. The acquisition time was 4.5 seconds, and the axial resolution was calculated to 6.9 μm in tissue. The accuracy of the external surfaces of the lens could be limited by the axial resolution. However, conservative calculations showed little impact on the reported astigmatism.

The lens axis could be easily centered with the OCT set to visualization mode, which displays two orthogonal B-scans in an interval of 0.5 seconds. The manually adjustable platform on which the cuvette was set up was aligned until a specular reflection was seen from the surfaces of the lens.

All lenses were imaged in two different focal planes, to allow visualization of lens surfaces and the cuvette holding the lens. The images were merged into one complete 3D image (anterior surface, posterior surface, and cuvette surface) using a custom-developed merging algorithm.²⁶ The lens was first completely imaged with the anterior surface facing the OCT beam, and then was flipped around a predetermined axis and imaged again with the posterior surface up. The aberration present on the image of the cuvette, which should be the same for both orientations of the lens, was used to correct possible alignment errors.

Laser Ray Tracing

After the OCT measurements, the focal length of each lens was measured with a custom developed LRT. The system combines a 2-mirror galvanometric scanning system with a 400-mm collimating lens. The illumination source is a superluminescent diode (849 nm). The system and its calibration have been described in previous publications.^{6,26} In brief, the crystalline lenses were placed horizontally in a cuvette (anterior up position), positioned on a stable platform. A motorized CMOS camera was placed right under the cuvette (whose base was optical quality glass) to capture a series of through-focus images from the beam directed through the lens. The lenses

were aligned with the LRT, such that the lens and the principal ray were collinear to the center of the CMOS camera, in the entire focus range (35 mm, which was the axial range of the motor). The focal lengths of each lens were measured projecting rings of light of different diameters (2 and 4 mm) onto the crystalline lens' upper surface. The refraction through the glass was compensated using a calibration method that involved measurements with a set of artificial lenses⁴⁸ (Edmund Optics, Inc., Barrington, NJ, USA). The estimated precision of the focal length measurements was 0.8 mm. The focal length data were used as input data for the GRIN reconstruction algorithm as described by Birkenfeld et al.²⁶

Image Processing and GRIN Reconstruction

All OCT images were corrected for optical distortion and fan distortion, and all surfaces (lens and cuvette) were fitted with Zernike polynomials (up to seventh order) within a 6-mm pupil. As described in detail in previous references,^{5,26} the method involves acquiring images of the crystalline lens in two different orientations, with the anterior surface up and with the posterior surface up. The aberration of the cuvette was used to compensate for potential alignment errors while flipping.⁵ Following correction of refraction by the preservation medium, the method allowed reconstruction of the undistorted lens shape.⁵ Furthermore, the posterior surface of the lens is distorted by the anterior surface and GRIN.

The GRIN was reconstructed by means of a search algorithm using the optical path measured from the OCT images and the measured back focal length.⁶ The gradient refractive index is described as a 4-variable model expressed in polar coordinates with the origin in the center of the GRIN as

$$n(\rho, \theta) = n_N - \Delta n \cdot \left(\frac{\rho}{\rho_S}\right)^{p(\theta)}, \quad (1)$$

where n_N is the refractive index of the nucleus, Δn the difference between the refractive index of surface and nucleus, ρ_S is the distance between nucleus and surface, and $p(\theta)$ is the exponential decay for axial ($p1$) and meridional ($p2$) direction. The axial decay $p1$ is constant across meridians, while $p2$ can vary to account for differences between meridians. This model was fully described in previous publications.^{5,6,26}

The change of the power exponent $p2$, that is, the decay of the GRIN in the meridional direction, is an indicator of the GRIN contribution to astigmatism. A constant $p2$ across the lens is indicative of no GRIN astigmatism. A sinusoidal variation of $p2$ across lens meridians is indicative of the presence of GRIN astigmatism. In all computations the center of the GRIN is assumed to be placed at a distance from the anterior vertex equal to 0.41 times the central thickness of the lens.⁴⁷

Calculation of Lens Astigmatism (Magnitude and Axis)

Lens GRIN Astigmatism. The lens astigmatism was calculated using the measured lens shape and the reconstructed GRIN by means of a computational ray tracing analysis.^{5,6} The calculated wave aberrations were fit by Zernike polynomials. The magnitude of astigmatism C and angle α were calculated⁴⁸ as

$$C = -2\sqrt{J_{45}^2 + J_{180}^2} \quad (2)$$

$$\alpha = \tan^{-1} \left(\frac{J_{45}}{J_{180}} \right) / 2, \quad (3)$$

where J_{180} is the power at axis $\alpha = 180^\circ$ and J_{45} is the power at axis $\alpha = 45^\circ$; J_{180} and J_{45} are related with the Zernike coefficients by the following expressions⁴⁹:

$$J_{180} = (-2\sqrt{6}/r^2)(Z_2^{-2}) \quad (4)$$

$$J_{45} = (-2\sqrt{6}/r^2)(Z_2^{-2}) \quad (5)$$

where Z_2^{-2} and Z_2^2 are the corresponding astigmatism Zernike terms, and r is the pupil radius (3 mm in this study).

Equivalent Refractive Index Lens Astigmatism. Lens astigmatism was calculated for all lenses considering a GRIN and a homogeneous equivalent refractive index. The equivalent refractive index is defined as the homogeneous refractive index with the same measured geometry and focal length as the GRIN lens.

By comparing the lens astigmatism with GRIN and with a homogeneous refractive index we can assess the contribution of GRIN to the lens astigmatism.

Virtual ray tracing was performed, to obtain Z_2^{-2} and Z_2^2 . From the Zernike fittings, C , J_{180} , J_{45} , and the astigmatic axis were calculated using Equations 2 through 5.

Surface Lens Astigmatism. The lens surface astigmatism C_S was calculated as

$$C_S = (n_2 - n_1) \left(\frac{1}{R_x} - \frac{1}{R_y} \right), \quad (6)$$

where R_x and R_y are the radii of curvature on the principal axis, and n_1 and n_2 are the refractive indices of the lens immersion medium and the lens cortex, respectively. The index of refraction of the lens cortex (n_2) was taken directly from our GRIN reconstruction, individually for every lens. The refractive index of aqueous (n_1) was assumed to be 1.336.⁵⁰

Relative Astigmatic Angle. Since the orientation of the isolated lens during the measurements is not corresponding to its actual orientation in vivo (up, down, nasal, temporal), the calculated axis of astigmatism of the lens surfaces is arbitrary. However, the relative angle between the different axes of astigmatism (anterior, posterior, GRIN lens, lens with homogeneous refractive index) can be computed, and defined, in a range between 0° and 90° .

Power Vector Analysis. To illustrate the magnitude of astigmatism and angle, the results are presented using a power vector graph.⁴⁸ As indicated above, we assumed that the axis of astigmatism of the anterior lens surface is vertically aligned in all lenses. We investigated potential rotations between the astigmatic axis of posterior lens surface, GRIN lens, and lens with equivalent refractive index with respect to the vertical aligned anterior surface astigmatic axis, and potential age-related changes.

RESULTS

Change of Magnitude of Astigmatism With Age

Figure 1 shows the change of the anterior and posterior lens surface astigmatism with age, fitted by linear regression. The anterior lens surface astigmatism decreases significantly with age ($r = 0.397$, $P = 0.018$). The posterior lens surface astigmatism does not change significantly with age ($r = 0.189$, $P = 0.276$).

Figure 2 shows the change of the lens magnitude of astigmatism with age for the crystalline lenses with the reconstructed GRIN ($r = 0.359$, $P = 0.034$) in comparison with the lens magnitude of astigmatism in the same lenses assuming a homogeneous equivalent refractive index ($r =$

FIGURE 1. Change in the lens surfaces astigmatism with age (anterior surface, slope = -0.005 D/y, $r = 0.397$, $P = 0.018$; posterior surface, slope = -0.002 D/y, $r = 0.189$, $P = 0.276$).

0.380, $P = 0.024$). The mean value of the magnitude of astigmatism was 1.46 diopters (D) for the GRIN lens and 1.02 D for the homogeneous refractive index lens.

Figure 3 shows a high correlation between the anterior lens surface astigmatism, and the GRIN lens astigmatism and the homogeneous refractive index lens astigmatism (GRIN lens, $r = 0.693$, $P = 3.9E - 6$; equivalent refractive index lens, $r = 0.565$, $P = 4.1E - 4$). The posterior lens surface astigmatism did not correlate with the lens astigmatism (not shown). The mean astigmatism of anterior lens surface and posterior lens surface were 0.43 ± 0.22 and 0.41 ± 0.19 D, respectively.

The GRIN lens astigmatism and the astigmatism of the lens with a homogeneous refractive index are similar and correlate well with each other ($r = 0.555$, $P < 0.01$, not shown). The average astigmatism of the GRIN and equivalent refractive index lenses were 1.22 ± 0.82 and 1.04 ± 0.65 D, respectively.

Relative Astigmatic Angles

As the absolute orientation of the lens is not known, the analysis of the astigmatic axis can only be made in relative terms. In particular, we studied potential changes with age of the astigmatic angles between anterior and posterior surface and the difference in astigmatic axis between the GRIN lens and the lens with homogeneous refractive index.

FIGURE 2. Change in the lens astigmatism with age (lens with GRIN, slope = -0.022 D/y, $r = 0.359$, $P = 0.034$; lens with equivalent refractive index, slope = -0.018 D/y, $r = 0.380$, $P = 0.024$).

FIGURE 3. Correlation between the GRIN lens astigmatism and the anterior lens surface astigmatism ($r = 0.693$, $P = 3.9E - 6$) and the equivalent refractive index lens astigmatism and the anterior lens surface astigmatism ($r = 0.565$, $P = 4.1E - 4$).

Figure 4 shows polar plots (using the power vector analysis notation) of astigmatic magnitude and axis of the lens surfaces, the GRIN lens, and the lens with homogeneous refractive index. The angle shown for the posterior lens surface, GRIN lens, and homogeneous refractive index lens are expressed relative to the anterior lens surface. Each dot in the plot represents one lens.

The average relative angle between anterior and posterior lens surface was 28.5° . In 68.57% of the lenses the relative angle was $< 45^\circ$.

The axis of the GRIN lens was almost aligned with the axis of the anterior lens surface. The average relative angle between anterior surface axis and GRIN axis was 8.9° . In 88.57% of the lenses the relative angle was $< 45^\circ$ (with 65.71% of all lenses having a relative angle $< 15^\circ$).

The presence of GRIN did not seem to have a large influence on the astigmatic axis. The relative angle between the astigmatic axis of the GRIN lens and the lens with homogeneous refractive index lens was on average 15.5° , with an angle difference between the GRIN lens and the homogeneous index lens $< 45^\circ$ in 82.8% of the lenses and $< 15^\circ$ in 45.6% of the lenses.

Figure 5 shows the age-dependency of the relative astigmatic angle between the lens surfaces. The angle between the anterior and posterior surface astigmatic axes tended to increase with age, but the correlation did not reach statistical significance (slope = -0.293 , $r = 0.173$, $P = 0.321$).

The meridional change of p_2 did not show any age dependency ($r = 0.007$, $P = 0.96$, not shown).

DISCUSSION

In this study, we investigated the contributions of lens surface astigmatism to astigmatism in the lens (in magnitude and axis, for GRIN lenses and lenses with an equivalent refractive index), and potential age dependencies.

We found a significant decrease of the astigmatic magnitude of the anterior surface with age, from positive values toward zero, while the posterior surface astigmatism did not change significantly with age. The lens astigmatism magnitude also had a tendency to decrease. The anterior surface astigmatism correlated well with the lens astigmatism. This observation is based on the fact that the axis of the lens astigmatism is close to the astigmatism axis of the anterior lens surface magnitude.

FIGURE 4. Power vector plot of (a) anterior surface (the astigmatic axis is vertically aligned), (b) posterior surface, (c) GRIN lens, and (d) lens with homogeneous refractive index. All angles are shown relative to the anterior surface.

In this study, the results ex vivo lack the absolute reference of astigmatic angle with respect to true anatomic features. Despite this, we provided a direct account of the relative axis of astigmatism in the anterior and posterior lens surfaces for the GRIN lens and the lens with homogeneous refractive index. We found that in most cases, the average astigmatic angle between anterior and posterior lens surfaces was $<45^\circ$, and that the axis of the GRIN lens was, on average, aligned with the axis of the anterior lens surface.

The magnitude and axis of the internal crystalline lens astigmatism has been a matter of controversy. Traditionally, Javal's rule is assumed, implying a linear relationship between corneal and refractive astigmatism, with a constant offset of 0.5 D of against-the-rule astigmatism (arising from internal astigmatism). Reports of the magnitude of corneal and refractive astigmatism differ across studies, with some works reporting no change of either, while others report significant changes of one or both.^{15,39–41} In those studies, internal astigmatism is computed indirectly from comparisons of corneal and ocular astigmatism, sometimes from different datasets, which may pose uncertainties.

The lack of knowledge of the real orientation to the cornea sets obvious limitations on our study, and on ex vivo lens studies in general. However, direct access on the crystalline lens shape and the reconstruction of GRIN in 3D has allowed us to understand the role of every component in the crystalline lens on its optical properties, astigmatism in particular.

Our results have significant implications for studies quantifying the crystalline lens shape in vivo. In an earlier publication, we showed the possibility of obtaining crystalline lens topography in vivo on three young eyes (ages 28–33), assuming a constant refractive index. The axes of anterior and posterior lens astigmatism were orthogonal in all eyes.⁵¹ In a similar age group (ages 19–36), we have found on average a smaller angle between anterior and posterior astigmatism ($44^\circ \pm 18.3^\circ$).

The relative small impact of GRIN on astigmatism we found in this study probably arises from the fact that astigmatism is driven by the relative difference in power across meridians, and the meridional component of GRIN is relative small. The results of the study imply that, at least for astigmatism, assuming a constant refractive index would not pose large errors in the reconstruction of the astigmatism of the posterior lens surface measured in vivo.
