Abstract

Tomato is the second most important vegetable crop worldwide and a rich source of industrially interesting antioxidants. Hence, the microwave-assisted extraction of hydrophilic (*H*) and lipophilic (*L*) antioxidants from a surplus tomato crop was optimized using response surface methodology. The relevant independent variables were temperature (*T*), extraction time (*t*), ethanol concentration (*Et*) and solid/liquid ratio (*S/L*). The concentration-time response methods of crocin and β-carotene bleaching were applied, since they are suitable *in vitro* assays to evaluate the antioxidant activity of *H* and *L* matrices, respectively. The optimum operating conditions that maximized the extraction were as follows: *t*, 2.25 min; *T*, 149.2 ºC; *Et*, 99.1 %; and *S/L*, 45.0 g/L for *H* antioxidants; and *t*, 15.4 min; *T*, 60.0 ºC; *Et*, 33.0 %; and *S/L*, 15.0 g/L for *L* antioxidants. This industrial approach indicated that surplus tomatoes possess a high content of antioxidants, offering an alternative source for obtaining natural value-added compounds. Additionally, by testing the relationship between the polarity of the extraction solvent and the antioxidant activity of the extracts in *H* and *L* media (polarity-activity relationship), useful information for the study of complex natural extracts containing components with variable degrees of polarity was obtained.

Keywords: *Lycopersicon esculentum*; microwave-assisted extraction; β-carotene/crocin bleaching assay; concentration-time response modelling; response surface methodology

1. Introduction

Tomato (*Lycopersicon esculentum* Mill.) is the second most important vegetable crop worldwide after potato and is consumed either fresh or in the form of processed products. In 2013, about 164 million of tones were produced in the world, having been registered an increase of 2.6 million of tones over 2012 (FAOSTAT, 2015). Apart from the large amounts of solid wastes produced by the processing industry, sometimes there is also a surplus production that leads to glut in the market, distress sale and low profit to the growers (Oliveira, 2006; Sashimatsung et al., 2011). One solution for the problem of this glut may be its sustainable use for the recovery of value-added antioxidant compounds with applications in food, pharmaceutical and cosmeceutical industries. In fact, tomato is a rich source of hydrophilic and lipophilic antioxidants (Barros et al. 2012; Pinela et al., 2012). The hydrophilic fraction is constituted mainly by ascorbic acid and soluble phenolic compounds, while the lipophilic fraction contains carotenoids (mostly lycopene), tocopherols, sterols and lipophilic phenolics. Each of these compounds has their own function in the human organism, acting at different locations, but also working conjunctly, having the ability to offer protection against oxidative stress and various degenerative diseases (Carocho and Ferreira, 2013a, 2013b; Friedman, 2013). Besides, according to some reports, antioxidants belonging to the hydrophilic fraction have a far more significant impact on total antioxidant activity than does antioxidants of the lipophilic fraction (García-Valverde et al., 2013; Kotíková et al., 2011).

The antioxidant activity can be monitored using a large variety of assays, each one based on a specific mechanism of action, including hydrogen atom transfer, single electron transfer, reducing power, and metal chelation, among others (Carocho and Ferreira, 2013a; Shahidi and Zhong, 2015). For this reason, it is important to understand

69 the mechanisms behind the selected assay for a suitable evaluation of the antioxidant
70 potential. Crocin and β-carotene bleaching reactions are two *in vitro* assays appropriate
71 for the antioxidant activity evaluation of hydrophilic (*H*) and lipophilic (*L*) matrices,
72 respectively, and can provide useful information in the study of complex natural
73 extracts containing components with variable degrees of polarity (Prieto et al., 2013;
74 Prieto and Vázquez, 2014). Both assays are reproducible, especially accurate, and yields
75 a low experimental error (Prieto et al., 2014).
76 To recover antioxidants from plant-based products is necessary to follow suitable
77 extraction methods that ensure and preserve its integrity and bioactivity. That's why the
78 industry is looking for more efficient processes based on enhanced innovation capacity.
79 Among them, microwave-assisted extraction (MAE) has gained significance due to its
80 shortened extraction time, higher extraction rate, reduced solvent consumption and
81 superior product's quality at lower cost (Dahmoune et al., 2015; Gallo et al., 2010),
82 being one of the dominant trends of the "green chemistry" movement (Michel et al.,
83 2011). However, the extraction process efficiency depends on some variables and
84 operating conditions (Bhuyan et al., 2015; Dahmoune et al., 2015), which may not be
85 generalized for all plant materials due to the diverse nature of existing bioactive
86 phytochemicals. Therefore, selection and optimization of variables and operating
87 conditions for the MAE of antioxidants from tomato is necessary.
88 One-factor-at-a-time approaches are commonly used to optimize extraction processes;
89 but it is well-known that optimal operating conditions or interactions between variables
90 cannot be predicted with this methodology. Both problems may be overcome by
91 employing the response surface methodology (RSM), a powerful statistical tool used to
92 predict the optimum experimental conditions to maximize or minimize various
93 independent variables. Indeed, RSM describes the relationship between independent

variables and one or more responses, enabling process optimization such as the extraction of bioactive molecules from natural sources with a reduced number of experimental trials.

This study aimed at determining the optimal extraction conditions for *H* and *L* antioxidants from a tomato surplus. Four independent variables (temperature, extraction time, ethanol concentration and solid/liquid ratio) were studied and the extraction process was optimized by RSM. The concentration-time response methods of β-carotene and crocin bleaching were applied, which are appropriate for the evaluation of antioxidant properties of *L* and *H* fractions, respectively.

2. Material and methods

2.1. Equipment and reagents

Equipments: Biotage Initiator Microwave (Biotage® Initiator+, Uppsala, Sweden) using closed high precision glass vials. Multiskan Spectrum Microplate Photometer using 96-well polypropylene microplates.

Reagents: Linoleic acid (CID 5280450); β-Carotene (CID 5280489); Crocin (CID 5281233); 2,2'-Azobis(2-amidinopropane) (AAPH or ABAP, CID 1969). All other chemicals and solvents were of analytical grade and purchased from common sources. Water was treated in a Milli-Q water purification system (Millipore, model A10, Billerica, MA, USA).

2.2. Plant material

A common tomato farmers' variety known as "tomate redondo or batateiro" (round tomato), and widely cultivated in rural communities from Miranda do Douro, North-eastern Portugal, was chosen for this study. Surplus tomatoes at the ripe stage were

hand-harvested randomly from the middle of six plants, in selected homegardens of two villages in the studied area. The ripening stage was established according to local consumers' criteria based in morphological descriptors such as size, texture, and pericarp colour. Six tomatoes (pericarps without jointed pedicels and seeds) were frozen and lyophilized (Free Zone 4.5, Labconco, Kansas City, MO, USA), reduced to a fine dried powder (20 mesh) using a grinding machine and kept at -20 °C until analysis.

2.3. Microwave-assisted extraction of *H* and *L* antioxidants

The MAE process was performed using a Biotage Initiator Microwave apparatus in closed vials. The dried powdered samples were extracted at different time (*t*), temperature (*T*), ethanol concentration (*Et*) and solid/liquid ratio (*S/L*) ranging as defined by the RSM design (Fig. 1). The solvent volume was fixed at 20 mL. During extraction, samples were stirred at 600 rpm using a magnetic stirring bar and irradiated at 200 W. After that, the reaction mixture in the closed vial was quickly cooled in the processing chamber and then centrifuged at 6000 rpm for 10 min. The pellet was discarded and the supernatant was carefully collected, evaporated under reduced pressure to remove the solvent and finally re-suspended in distilled water for further analysis. The dry weight (dw) of the suspended solids in the supernatant of each solution was determined to compute the extraction yield (g extract/g samples).

2.4. Determination of the concentration-time dependency of *L* and *H* antioxidants

β-Carotene (Marco, 1968) and crocin (Bors et al., 1984) methods (βCM and CM, respectively) are widely used to evaluate the antioxidant activity of different matrices. Both *in vitro* assays share some analytical similarities as depicted in the next points.

144 *2.4.1. Reaction conditions*

145 βCM conditions (Prieto et al., 2012): 2 mg of β-carotene (βC, 1 μM in the final
146 reaction), 0.25 mL of linoleic acid and 2 g of Tween-40 were dissolved in 20 mL of
147 chloroform, vigorously mixed, followed by chloroform evaporation (45 °C/~15 min).
148 To the resulting oily residue were added 300 mL of buffered Mili-Q water (100 mM
149 Briton, pH=6.5) at 45 °C. The absorbance at 470 nm of the prepared reagent was ~1.40.
150 CM conditions (Prieto et al., 2015): 4 mg of crocin (Cr, 100 μM in the final reaction)
151 and 75 mg of AAPH (7.68 mM in the final reaction) were dissolved in 30 mL of a 100
152 mM Briton buffer, pH=5.5, in Mili-Q water. The absorbance at 450 nm of the prepared
153 reagent was ~1.40.

154

155 *2.4.2. Procedure*

156 The procedure was performed by adding 50 μL of sample extract and 250 μL of reagent
157 into the wells (350 μL) of the microplate. The microplate-reader was programmed at
158 intervals of 3, 5 and 10 min (initiation, propagation and asymptotic phases), during a
159 period of 200 min (total of 30 measures). The sample extracts were analyzed kinetically
160 for eight different concentrations obtained by serial dilution (1/1, 1/2, 1/4, 1/8, 1/16,
161 1/32, 1/64 and the control) in distilled water.

162

163 *2.4.3. Quantification*

164 The area under the curve (*AUC*) (Eq. 1), computed by any numerical integration method
165 such as the trapezoidal rule, proved to be a highly robust criterion, able to summarize in
166 a single and direct value the global feature of any kinetic profile.

$$AUC = \frac{R_1 \Delta t_1}{2} + \sum_{i=2}^{i=n-1} R_i \Delta t_i + \frac{R_n \Delta t_n}{2} \quad (1)$$

where i is the number of data measured over time t, R_i are the responses along an arbitrary time series, and Δt is the interval of each measurement.

The AUC of a concentration-response of an antioxidant was normalized against to the AUC obtained with the control, leading to the formulation of the relative area units or protected substrate ($\bar{P}$) in percentage (Eq. 2), as defined similarly by other authors (Dávalos, 2004; Huang et al., 2002; Naguib, 2000) for antioxidant responses.

$$\bar{P}(A) = S_0\left(\frac{AUC_C - AUC_A}{AUC_C}\right)\frac{100}{S_0} \qquad (2)$$

where AUC_C and AUC_A are the area units corresponding to the kinetic profiles found in the absence (control, C) and presence of an antioxidant concentration A, respectively, and S_0 is the initial substrate in the reaction (for the CM, the substrate is equivalent to 100 μM of Cr, and for the βCM it is equivalent to 1 μM of βC).

The relationship in Eq. (2) establishes that AUC_C (control) is also the maximum response achievable; consequently the values obtained were also standardized in percentage. In addition, by normalizing the response, the results obtained are less dependent on the experimental conditions, which, in practice, is one of the common problems when analyzing the efficacy of response factors.

The asymptotic variation of $\bar{P}$ as function of an antioxidant compound suggests that some radical-generating property of the system can be saturated (Gieseg and Esterbauer, 1994). This type of concentration-response patterns should behave in a similarly accumulative way with a number of different antioxidant compounds found in the extract material. Therefore, in general, this patterns can be adjusted by a group of mathematical expressions (mechanistic or not) that translates the pattern of the response into parameters that allow to deduce the meaning and/or quantify the effect of the dependent variable in a simple and global mode. Previous researchers discussed the

applicability of different mathematical expressions (Prieto et al., 2014); therefore, following their views, the Weibull cumulative distribution function was selected (Weibull and Sweden, 1951). Thus, the variation of $\overline{P}$ as function of increasing concentrations of an antioxidant (A) can be described satisfactorily using the Weibull model rearranged for our own purposes as follows in Eq. (3).

$$\overline{P}(t,A) = P_m \left\{ 1 - \exp\left[-\ln(2)^{1-a} \left(\frac{2V_m}{P_m a} A \right)^a \right] \right\} \quad (3)$$

The parameter P_m is the averaged maximum protected substrate, asymptotic value of the response (% μM of βC or Cr), which is specific of each A agent. The parameter V_m corresponds to the average amount of protected molecules per gram of extracted material (% μM of protected substrate/g extract). The parameter a is a shape parameter related to the slope that can produce potential profiles (a<1), first order kinetic ones (a=1) and a variety of sigmoidal profiles (a>1).

In addition, the concentration needed to reach 50% of the maximum protective effect (the so called IC_{50}) can be determined according to Eq. (4).

$$IC_{50} = \frac{Ka \ln 2}{2V_m} \text{ ; therefore } \overline{P}(t,A) = P_m \left\{ 1 - \exp\left[-\ln(2)\left(t/IC_{50}\right)^a \right] \right\} \quad (4)$$

where IC_{50} is the concentration producing the half-maximal response and all other notations remain with the same meaning as above.

2.5. Response surface methodology

The RSM family designs are used for modelling and analyzing problems in which a response of interest is influenced by a set of variables. RSM was applied to optimize the MAE process with the purpose of finding the favourable processing conditions that would result in a higher extraction rate of H or L antioxidants.

211

212 *2.5.1. Response criteria for evaluating the antioxidant capacity*

213 The responses used in the RSM analysis were based in the numerical values of the
214 parametric coefficients P_m, V_m and IC_{50} of Eqs. (3) and (4). The information provided
215 by the combination of the values of the three response criteria represents a robust tool to
216 compare the activity of different antioxidant agents based on the parametric
217 concentration-time estimations.

218

219 *2.5.2. Preliminary experiments*

220 Preliminary single-factor experiments were conducted in order to select the significant
221 variables and/or collateral factors in extraction process and to determine the preliminary
222 range of the optimum level of each factor for an appropriate experimental RSM design.
223 In this primary screening trial, the following variables and factors were considered:

224 - Internal independent variables of the microwave equipment: Pressure (1-30 bar),
225 stirring rate (0-1000 rpm), microwave power (0-400 W), temperature (40-300 ºC)
226 and extraction time (no limits).
227 - Internal factors of the instrument software: Absorption level (*very low*, *low*, *normal*,
228 *high*, or *very high*), fixed hold time (if *on* the time countdown starts when the target
229 temperature or pressure is reached, *i.e.*, the initial time taken to reach the set
230 conditions is not included in the heating time; if *off* the time countdown starts when
231 the heating starts), cooling (*on* or *off*), pre-stirring (during the fixed hold time, if
232 selected; *on* or *off*) and vial type (2-5 mL or 10-20 mL).
233 - External independent variables and factors: Solid/liquid ratio and ethanol
234 concentration. The type of solvent used in the extraction.

235

236 *2.5.3. Experimental design*

237 From the preliminary study, the independent variables X_1 (extraction time, min), X_2
238 (temperature, ºC), X_3 (ethanol concentration, %) and X_4 (solid/liquid ratio, g/L) were
239 selected. Then, the combined effects of these variables on the extraction yield of *H* and
240 *L* antioxidant were studied using *central composite design* as proposed by Box et al.
241 (1957). In this design, the points of experiments are generated on a sphere around the
242 centre point. The centre point is supposed to be an optimum position for the response
243 and is repeated in order to maximize the prediction precision (Box and Hunter, 2005).
244 This design also requires five levels for each factor. The number of repetitions n_0 of the
245 centre point is calculated by the formulas present in Eq. (5) for *k* factors based on the
246 uniform precision.

$$\gamma = \frac{(k+3)+\sqrt{9k^2+14k-7}}{4(k+2)}; \quad \text{where:} \quad n_0 = floor\left(\gamma\left(\sqrt{2^k}+2\right)^2 - 2^k - 2k\right) \tag{5}$$

247 where *floor* designates the highest integer value smaller than the argument. The number
248 of experiments *n* for *k* factors is given as:

$$n = 2^k + 2k + 1 \tag{6}$$

249 Experimental runs were randomized, to minimize the effects of unexpected variability
250 in the observed responses. Independent variables coded values and natural ones of the
251 factorial design are coded and decoded by the expressions in Eq. (7).

$$v_c = (v_n - v_0)/\Delta v_n \quad \text{and} \quad v_n = v_0 + \Delta v_n \times v_c \tag{7}$$

252 where v_n and v_c is the natural (*n*) and coded (*c*) value in the centre of the experimental
253 domain, v_0 is the initial value and Δv_n is the increment of v_n for unit of v_c.

254

255 *2.5.4. Box-Behnken mathematical model*

Response surface models were fitted by means of least-squares calculation using the following Box-Behnken equation:

$$Y = b_0 + \sum_{i=1}^{n} b_i X_i + \sum_{\substack{i=1 \\ j>i}}^{n-1} \sum_{j=2}^{n} b_{ij} X_i X_j + \sum_{i=1}^{n} b_{ii} X_i^2 \quad (8)$$

where Y is the dependent variable (response variable) to be modelled, X_i and X_j define the independent variables, b_0 is the constant coefficient, b_i is the coefficient of linear effect, b_{ij} is the coefficient of interaction effect, b_{ii} the coefficients of quadratic effect and n is the number of variables. As pointed out, three different response formats based in the parametric estimations (P_m, V_m and IC_{50}) of Eqs. (3) and (4) were used as the dependent variable for each H and L antioxidant analytical reaction (Y_{Pm}^{H}; $Y_{V\tau}^{H}$; $Y_{IC_{50}}^{H}$; Y_{Pm}^{L}; $Y_{V\tau}^{L}$; and $Y_{IC_{50}}^{L}$).

2.6. Numerical methods and statistical analysis

All fitting procedures, coefficient estimates and statistical calculations were performed on a Microsoft Excel spreadsheet. Fitting and statistical analysis of the experimental results to the proposed equations were carried out in four phases:

1) Coefficients determination: Parametric estimates were obtained by minimization of the sum of the quadratic differences between observed and model-predicted values, using the nonlinear least-squares (quasi-Newton) method provided by the macro *Solver* in *Microsoft Excel* 2003 (Kemmer and Keller, 2010), which allows a quick testing of a hypotheses and its consequences (Murado and Prieto, 2013).
2) Coefficients significance: The determination of the parametric confidence intervals were calculated using the '*SolverAid*' (Prikler, 2009). The model was simplified by dropping terms, which were not statistically significant p-value > 0.05.

3) Model consistency: The Fisher *F*-test (α=0.05) was used to determine whether the constructed models were adequate to describe the observed data (Shi and Tsai, 2002).

4) Other statistical assessment criteria: To re-check the uniformity of the model the following criteria were applied: a) The 'SolverStat' macro was used for the assessment of the parameter and model prediction uncertainties (Comuzzi et al., 2003); b) The R^2 was interpreted as the proportion of variability of the dependent variable explained by the model; c) The adjusted coefficient of determination (R^2_{adj}) was a correction to R^2 taking into account the number of variables used in the model; d) Bias and accuracy factors of all equations were calculated to evaluate the fittings to experimental data, such as the Mean Squared Error (MSE), the Root Mean Square of the Errors (RMSE) and the Mean Absolute Percentage Error (MAPE); e) The Durbin-Watson coefficient (DW) was used to check if the residuals of the model are not autocorrelated; and f) The analysis of variance table (ANOVA) was used to evaluate the explanatory power of the variables.

3. Results and discussion

3.1. Preliminary study

As listed in the material and methods section, the MAE efficiency may be affected by five internal (pressure, stirring rate, microwave power, extraction time, and temperature) and two external (solid/liquid ratio and ethanol concentration) independent variables and five instrument/software factors (absorption level, fixed hold time, vial type, cooling option, and solvent type). Although there are previous research examples (Bhuyan et al., 2015; Dahmoune et al., 2015), the results are not generalizable for all plant materials due to the diverse nature of existing bioactive phytochemicals.

303 Therefore, this preliminary study allowed screening of appropriate independent
304 variables and determining their optimum experimental domain for an appropriate
305 experimental RSM design. Variables/factors were investigated by testing a broad range,
306 keeping other ones constant and analyzing their antioxidant responses.

307 - Type of extracting solvent is the key for separating *H* and *L* compounds. Water is
308 the polar solvent with greater interest in biological processes than any other solvent.
309 Ethanol has a polar hydroxyl group and dissolves many ionic compounds, but also
310 has a non-polar end, which will contribute to dissolve non-polar substances. In this
311 study, binary interactions of ethanol-water mixtures were selected due to their
312 straight *H* affinity, but also because ethanol increases the *L* character of the aqueous-
313 ethanolic mixture. All the tested ethanol concentrations give rise to significant
314 differences; thus, the range from 0 to 100 % was selected.

315 - Pressure and temperature were correlated. The selected irradiation power was
316 applied in the early stage of the extraction process to reach the selected
317 temperature/pressure in a short period of time. After that, it was automatically
318 applied in less intensity (estimated by the microwave system) to keep constant the
319 solution temperature/pressure. In consequence, the microwaves power was set at
320 200 W and the temperature was selected as the main controlled variable, since
321 relevant differences were found within the range 60 to 180 ºC.

322 - Lower solid/liquid ratios can lead to a more efficient dissolution of constituents, but
323 also to a waste of solvent. At an industrial scale, higher ratios are desirable since it
324 is important to maximize the extraction yield (thus productivity) with a minimal
325 solvent consumption (more sustainable process). Significant differences were found
326 for all tested ratios in this preliminary study, being the range from 5 to 45 g/L
327 selected for RSM analysis.

- The temperature caused strong decomposition phases of antioxidants for extraction times higher than 20 min, but this effect depended on the other variables that remained constant. Therefore, extraction times ranging from 0 to 20 min were selected.
- The cooling option showed relevant effects. It is used at the end of the MAE process to cool the sample. When *off*, the cooling time of the solution after processing was longer, affecting the extraction of antioxidants. Therefore, it was used *on* to quickly cool the solution and stop faster the extraction process, making the process more accurate.
- When testing the effects of other factors, such as the absorption level, fixed hold time and vial type, no significant changes were found. Therefore, a *normal* absorption level and vials of 10-20 mL were selected for further analysis. The fixed hold time was turned *off*, since the initial time taken to reach the set temperature or pressure was negligible.

Therefore, the RSM experiment was designed based on these preliminary results, using five variation levels of extraction time (0-20 min), temperature (60-180 ºC), ethanol concentration (0-100%) and solid/liquid ratio (5-45 g/L) as independent variables to optimize efficiently the MAE process, regarding the *H* and *L* antioxidant properties of the extracts. The coded values and their natural values are presented in Fig. 2. Note that, for simplification reasons, the RSM design reduces the number of experimental trials. When studying 5 levels of 4 independent variables, the response would imply 625 possible combinations, but using RSM the experiment could be solved in 25 independent combinations and 7 replicates at the centre of the experimental domain.

3.2. Concentration-time antioxidant responses for RSM

353 Several reviews have discussed the numerous *in vitro* methods developed to evaluate
354 the antioxidant activity of plant extracts and their controversial aspects regarding
355 differences in the generated radicals, variables (mainly pH and temperature), reagents,
356 and quantification procedures (Carocho and Ferreira, 2013a; Frankel and Meyer, 2000;
357 Jiménez-Escrig et al., 2000). However, when determining the bioactivity of a sample,
358 the final activity response also depends on the degree of polarity of the intermediate
359 reaction components of the applied method. For example, when evaluating the
360 bioactivity of extracts obtained with *H* and *L* extraction solvents using the oxidative
361 hemolysis inhibition assay (OxHLIA) (method in which the thermal decomposition of
362 AAPH generates *H* radicals and the lipid peroxidation of the erythrocytes membranes
363 generates *L* radicals (Niki et al., 1988)), no clear conclusions can be made because both
364 *H* or *L* antioxidants delay the hemolysis and, therefore, produce an antioxidant response.
365 To the best of our knowledge only few articles have addressed the *H* and *L* intermediate
366 components activity (Arnao et al., 2001; Prieto et al., 2013; Prior et al., 2003).
367 Therefore, the lack of selective methods to differentiate the activity of *H* and *L*
368 antioxidants is a current issue in the evaluation of antioxidant responses that need to be
369 outlined in the following years.
370 In order to reduce the variability of experimental conditions, allowing meaningful
371 comparisons, and to quantify the power of the antioxidants in function of the degree of
372 polarity, the response models of CM and βCM were selected because they provide a
373 microsystem for *H* and *L* oxidation processes, respectively (Prieto et al., 2013). The βC
374 is an *L* oxidizable substrate that can join the system of lipid micelles in which the
375 oxidation reaction is accomplished. The method is especially sensitive to antioxidants in
376 a lipidic environment, producing a very low response to *H* antioxidants, even to

377 powerful ones. In turn, Cr is an *H* oxidizable substrate and *L* antioxidants produce very
378 low responses in the reaction system.
379 Fig. 3 and Fig. 4 show an illustration of the antioxidant responses obtained for the
380 tomato extracts produced under the experimental RSM design presented in Fig. 2 for
381 each *H* and *L* antioxidant reaction (CM and βCM), respectively. In both figures, two
382 well differentiated sections are presented at the left- and right-hand sides, showing the
383 visual variable distribution of the 25 genuine combinations. The left-hand side shows
384 the combinations of the concentration-time responses of seven serial dilutions (○:1/1,
385 ▲: 1/2, △: 1/4, ■: 1/8, □: 1/16, ◆: 1/32, ◇: 1/64) and the control (●) for the
386 remaining substrates (% μM Cr and βC). Meanwhile, the right-hand side shows the
387 concentration-time transformation into the concentration-response values of the *AUC*
388 computed by the numerical integration method in Eq. (1) and standardized in percentage
389 of protected substrate (Cr or βC) by Eq. (2). The dots (●) are the raw values and lines
390 (—) the fitted responses to the mathematical model of Eq. (3) or (4). The parametric
391 fitting values of Eqs. (3) and (4) are presented in Table 1. The estimated numerical
392 values of P_m, V_m and IC_{50} were the three meaningful ways considered to evaluate the
393 effectiveness of the antioxidant response by RSM.
394
395 **3.3. Development of the theoretical response surface models and statistical**
396 **verification**
397 Table 1 shows the results of the parametric fitting coefficients (data presented in Fig. 3
398 and Fig. 4) for each *H* and *L* reaction obtained after running 32 trials (25 genuine
399 combinations and 7 replicates) following the experimental RSM design. Estimated
400 coefficient values of Eq. (8), parametric intervals and numerical statistical criteria are
401 shown in Table 2, for each coefficient used as response criteria and for *H* and *L*

402 reactions. The coefficients that showed effects with *p-values* higher than 0.05 are not
403 significant (*ns*) at the 95% confidence level and consequently were discarded for model
404 development.
405 Mathematical models were built through nonlinear least-squares estimations based on
406 the coded experimental plan and the response results, obtaining the following second-
407 order polynomial Eq. (8):
408 when the hydrophilic *CM* was considered:

$$Y_{Pm}^{H} = 30.5 + 8.7x_3 + 6.9x_4 + 7.3x_1^2 + 13.1x_4^2 + 13.1x_1x_2 - 4.5x_2x_3 \quad (9)$$

$$Y_{V\tau}^{H} = 26.5 - 8.1x_1 - 17.2x_3 - 6.9x_2^2 + 9.1x_3^2 + 7.0x_4^2 \quad (10)$$

$$Y_{IC_{50}}^{H} = 0.40 + 0.04x_2 + 0.27x_3 + 0.05x_2^2 + 0.05x_3^2 + 0.16x_1x_2 - 0.05x_2x_3 \quad (11)$$

409 when the lipophilic *βCM* was considered:

$$Y_{Pm}^{L} = 96.1 + 8.1x_1 - 7.1x_2 + 5.1x_3 - 5.6x_4 - 10.7x_1^2 - 9.8x_2^2 - 8.6x_3^2 - 11.8x_4^2 - 7.7x_1x_2 + 13.1x_2x_3 \quad (12)$$

$$Y_{V\tau}^{L} = 13.1 - 2.9x_1 - 3.2x_3 - 2.0x_4 + 5.9x_2^2 + 2.3x_1x_3 + 1.6x_1x_4 - 1.7x_2x_3 + 6.2x_2x_4 \quad (13)$$

$$Y_{IC_{50}}^{L} = 2.97 + 0.76x_3 + 0.31x_4 - 0.24x_1^2 - 0.07x_3^2 - 0.22x_4^2 - 0.24x_1x_4 + 0.43x_2x_3 + 0.27x_3x_4 \quad (14)$$

410 where X_1 (extraction time), X_2 (temperature), X_3 (ethanol concentration), X_4 (solid/liquid
411 ratio), Y is the response, sub-indices indicates the coefficient criteria (P_m, V_m and IC_{50})
412 used as responses for RSM and super-indices H and L accounts for the H (CM) and L
413 (βCM) reactions.
414 The multivariable characterization of the Box-Behnken second-order polynomial model
415 is especially robust, minimizing the experimental errors, allowing explain the utmost of
416 the results. In addition, once a model is designed, if the experimental data obtained do
417 not span the full range and some of them fail to provide information about one or more
418 of the parameters of the equation, the multivariable application describes simply and

419 accurately all the areas. As explained, not all the parameters of Eq. (8) were used for
420 building the model, since some terms were non-significant (Table 2). Model coefficients
421 obtained are empirical and cannot be associated with physical or chemical significance.
422 However, they are useful to predict the results of untested operation conditions (Ranic
423 et al., 2014). The sign of the effect marks the performance of the response. In this way,
424 when a factor has a positive effect, the response is higher at the high level and when a
425 factor has a negative effect, the response is lower at high level. The higher the absolute
426 value of a coefficient, the more important the weight of the corresponding variable.
427 Based in the mathematical expressions, it was found that the responses in the *L*
428 environment were much more complex than those found in the *H* one.
429 The statistic lack of fit, used to test the adequacy of the obtained models, demonstrated
430 that no considerable improvement was achieved by the inclusion of the statistically non-
431 significant effects (Table 2). This was also verified by the high R^2 and R^2_{adj} values
432 indicating the percentage of variability of each response that is explained by the model
433 (Table 2). The distribution of residuals always randomly scattered around zero and
434 grouped data and autocorrelations were not observed. This means that these models are
435 workable and can be applied in the subsequent prediction and optimization stages.
436 Finally, the analysis of variance (ANOVA) was computed for the regression equations.
437 The lack of fit was used to verify the adequacy of the model and was not significant (p
438 > 0.05), indicating that Eqs. (12) to (14) adequately fit the experimental data.
439
440 **3.4. Effect of *Et* and *T* variables as representative case of the typical *H* and *L***
441 **trends**
442 The three response criteria (P_m, V_m and IC_{50}) characterize singular features of the
443 response. Previous to the complete analysis of the *H* and *L* antioxidant extraction trends,

444 the information provided by each parametric response criteria, which were used in the
445 RSM design, was individually analyzed. As an illustrative case study, it was selected
446 the effect of the variables *Et* and *T*, meanwhile the variables *t* and *S/L* were positioned at
447 the centre of their experimental domain (*t*=10 min and *S/L*=25 g/L). Graphical 3D
448 representations are displayed in Fig. 5 and the parametric fitting values are present in
449 Table 2. In general, it can be observed that the *H* and *L* antioxidant activity of the
450 tomato extracts have opposite trends for *Et* and *T*. In more specific terms, for each
451 criterion it can be concluded that:

452 a) The parameter P_m of Eq. (3) shows the maximum specific capability of the
453 antioxidant agent to protect the substrate (% μM of Cr or βC) and, the higher the P_m
454 value, the more powerful the protective capability of the antioxidant. In general, we
455 can speculate that the more complex the content in antioxidant molecules in the
456 extract (which act at different *H* or *L* oxidation levels), higher the parameter P_m.
457 These types of extracts are usually obtained with longer extraction times. The
458 conditions that favour the *H* activity of the P_m value were at high ranges (↑) of *Et*
459 and low ranges (↓) of *T* or, in a much less active manner, at ↓ *Et* and ↑ *T*. In contrast,
460 the *L* activity was found at intermediate ranges (↔) of *Et* and *T*, leading to a clear
461 optimum at 50 % *Et* and 120 ºC. The inversion effect of the polarity-activity
462 relationship proposed by the polar paradox theory is visible in these results (Porter,
463 1993). Actually, the speculated effect of the non-polar end of ethanol on the activity
464 of the tomato extracts was not observed; they even showed an improvement of the *H*
465 antioxidant activity at ↑ *Et*, while the *L* antioxidant activity decreased sharply at
466 both ends of *Et*.

467 b) The parameter V_m of Eq. (3) corresponds to the average amount of protected
468 molecules of Cr or βC per gram of extracted material (% μM of protected

substrate/g extract), which is a value of maximal predictability. The higher the V_m value, the more powerful the antioxidant. There are a diverse number of compounds that would present a high specific protection, but only few would be present in an enough amount to show its activity. Therefore, the highest values should appear when an extraction peak of an antioxidant with a high specific protection would be found. The conditions that maximize the V_m response of the *H* activity were at ↓ *Et* and ↔ *T*; while for the *L* activity were found at ↓ *Et* and ↑ *T*. The effect of the inversion of the polar activity on the optimal response was not as evident as for the parameter P_m, but the opposite trends remain present as can be seen in each 3D surface.

c) The parameter IC_{50} of Eq. (4) provides directly the classical IC_{50} (g of extract), which will effectively summarize all effects of the other two responses. It provides the amount of extract needed to achieve a very specific response (50%). The lower the IC_{50} value, the more powerful the antioxidant. The lowest values should be found in an intermediate position between those speculated in the previous criteria. For the IC_{50} criteria, the conditions that maximize the response for the *H* antioxidant activity were at ↓ *Et* and ↓ *T*, while for the *L* activity were at ↓ *Et* and ↑ *T*.

The data published in literature often focus on only one response parameter, but each of them describes different intrinsic characteristics of the response. The information provided by the combination of the three values represents a robust tool to compare the activities of different antioxidant agents based on the parametric concentration-time estimations. By analyzing all parametric nonlinear values for the experimental RSM design, a more rigorous evaluation of the extraction efficiency of *H* and *L* antioxidants is accomplished.

3.5. Nonlinear relationship between extraction solvent polarity and antioxidant activity

Matrix combination of the 3D responses for the *H* and *L* environmental reactions obtained for the P_m, V_m and IC_{50} are presented in Fig. 6, Fig. 7 and Fig. 8, respectively. In addition, a simplified way to present the results in a 2D format for all responses is presented in Fig. S1 of the supplementary material. Eqs. (12) to (14) were used to simulate the surfaces. In each graphical illustration, the top diagonal part presents the response surfaces for *L* reactions and the bottom diagonal part presents the response surfaces for *H* reactions. The variables excluded in each 3D graph were positioned at the centre of their experimental domain (*t*=10 min; *T*=120 ºC; *Et*=50 %; and *S/L*=25 g/L).

In general, the inversion effect of the polarity-activity relationship was observed in almost all responses. The effects accounted between the *t*, *T* and *S/L* variables would describe the conditions that optimize the *H* and *L* antioxidant responses of the tomato extracts. However, the variable *Et* did not perform as theoretically expect. Such fuzziness between the polarity of extraction solvent and the antioxidant activity of the extracts in *H* and *L* environments (the so-called polarity-activity relationship) was found interesting enough to be considered. Generally, the extraction ability of solvents can be grouped in three main types: non-polar, polar aprotic and polar protic solvents (Huffman et al., 2012; Kislik, 2012). The choice of the extracting solvent is the first crucial step towards the optimization of any extraction method (Sultana et al., 2009), which has a strong impact on the type of molecules that would be separated. In turn, antioxidants are classified into two broad divisions (Arnao et al., 2001), depending on whether they are soluble in water (*H*, such as ascorbic acid) or in lipids (*L*, such as α-tocopherol). When performing an extraction, it is well known that *L* antioxidant

519 molecules are mostly extracted in non-polar solvents (*i.e.*, *n*-hexane) and *H* antioxidant
520 molecules in polar ones (*i.e.*, water), according to the "like dissolves like" principle, as
521 confirmed by several authors that separated effectively the molecular *H* and *L* character
522 of molecules by applying different solvent combinations in conjunction with different
523 extraction procedures (Watanabe et al., 2014). However, based on the achieved results,
524 the separation of extracts according to their molecular polarity character does not
525 guarantee that their polar or non-polar target activity can be separated as well. As stated
526 before (Prieto et al., 2013), when testing the activity of *H* and *L* antioxidant extracts
527 (hexane and methanol solvents, respectively), it was confirmed that *H* and *L* antioxidant
528 extracts, normally in a much lesser extent, remain active in the opposite environment. In
529 addition to that complex scenery, there are amphiphilic molecules presenting an affinity
530 with solvents of various polarities (Taresco et al., 2015).
531 Thus, if their polarity-activity is not totally related with their distribution in the
532 extracting solvents as defined by the polarity index (*i.e.*, dielectric constant), we may be
533 using extracts for *L* environments (*i.e.* oils) with a high content in molecules with a *H*
534 antioxidant activity and vice versa. Nonetheless, it is recognized that antioxidants with a
535 clear *H* and *L* character can cause the opposite effect when applied in the opposite
536 environment (*i.e.*, ascorbic acid can initiate lipid oxidation in conjunction with metal
537 cations) (Zhang and Omaye, 2001). Actually, according to the polar paradox theory
538 (Porter, 1993), polar antioxidants are more effective in less polar media, while non-
539 polar or amphiphilic antioxidants tend to be more effective in a media of relatively
540 higher polarity. The higher efficiency of *L* antioxidants in oil-in-water emulsions would
541 be due to their tendency to concentrate at the interfacial membrane where the oxidation
542 is supposed to occur, while more *H* antioxidants would tend to segregate into the

543 aqueous phase where they would be much less effective (Frankel et al., 1994). Our
544 results support this phenomenon.
545 A possible hypothetical foundation behind the mechanisms that caused this effect could
546 be the microwave absorbing properties of the solvent (Dahmoune et al., 2015). Polar
547 molecules strongly absorb microwave energy because of the permanent dipole moment,
548 and the degree of absorption increases with the dielectric constant. A simple comparison
549 between water and ethanol shows that ethanol has a lesser ability to obstruct the
550 microwaves as they pass through, but has a greater ability to dissipate the microwave
551 energy into heat. This strong absorption provides an increase of the temperature inside
552 the sample, leading to the rupture of cells by the *in situ* water. In some cases it can
553 promote the degradation of the target antioxidants and, in other cases, can increase the
554 diffusivity of the target antioxidants in the matrix.
555 Knowing all that, when describing the antioxidant activity of components of a complex
556 natural extract as a function of the degree of polarity, scientific studies typically involve
557 a first extraction step with solvents with different polarity index, followed by testing
558 their activity by different analytical procedures. However, such a link between polarity-
559 activity cannot be straightforward performed and further analyses are need. In the
560 literature there are few reports addressing the previously mentioned associated issues
561 (Jayasinghe et al., 2013; Li et al., 2015). However, it would be interesting to perform
562 studies considering the following issues: a) a well-defined group of *in vitro* methods
563 that could separate the polar activity of compounds in *H* and *L* antioxidants; b) a
564 representative set of natural materials sources extracted with a set of solvents
565 demonstratives of the different polarity index; c) a complex optimization of variable
566 conditions that affect the extraction of *H* and *L* antioxidants to ensure and preserve its
567 integrity and bioactivity; and d) clear target applications with a marked *H* and *L*

568 character to prove in an *in vivo* form, whether or not the relation between the aspects
569 stated in a), b) and c) are validated. The combination of all these requirements seems to
570 be a labour-intensive approach, being out the context of this work.
571
572 **3.6. Optimal extraction conditions for *H* and *L* antioxidants**
573 The fitting results (Table 2) obtained by applying Eq. (8) to all the response criteria (P_m,
574 V_m and IC_{50}) are presented in Eqs. (9) to (11) for the *H* reaction and in Eqs. (12) to (14)
575 for the *L* reaction. By finding the partial derivatives of these regression equations,
576 equating them to zero (Table S1 of the supplementary material) and solving the
577 equations system, the coded values that optimize the response criteria were obtained.
578 Then, the coded variable values were introduced in the original Eqs. (9)-(14) and the
579 optimal response values were found. Finally, by decoding the coded values, the
580 conditions that maximize the response were transformed into natural values.
581 The operating conditions that maximize the extraction of the tomato antioxidants and
582 the optimal response values are presented in Table 3, for each parametric estimation
583 criteria (P_m, V_m and IC_{50}) and analytical reaction (*H* and *L*). For *H* antioxidants, the
584 optimal conditions for P_m were at 180.0 ºC, with 56.8 % ethanol and 45.0 g/L of
585 sample, during 18.7 min; for V_m were at 120.0 ºC, with 0.0 % ethanol and 5.0 g/L of
586 sample, during 2.5 min; and for IC_{50} were at 90.0 ºC, with 44.0 % ethanol and 17.0 g/L
587 of sample, during 14.5 min; and for *L* antioxidants, the optimal conditions for P_m were
588 at 93.6 ºC, with 44.0 % ethanol and 21.3 g/L of sample, during 13.4 min; for V_m were at
589 180.0 ºC, with 100 % ethanol and 5.0 g/L of sample, during 2.2 min; and for IC_{50} were
590 at 169.1 ºC, with 91.7 % ethanol and 10.9 g/L of sample, during 2.6 min. Optimal
591 extraction conditions based on all the response criteria (P_m, V_m and IC_{50}) were also
592 determined for *H* and *L* antioxidants. Based on these values, it was found that the

593 extraction of *L* antioxidants demands a longer *t* (15.4 min) but a lower *T* (60.0 ºC), *Et*
594 (33.0 %) and *S/L* (15.0 g/L), comparing to the operating conditions outlined for *H*
595 antioxidants (*i.e.*, t, 2.25 min; T, 149.2 ºC; Et, 99.1 %; and *S/L*, 45.0 g/L). These
596 intermediate extraction conditions, and others that were optimized for each response
597 criteria (P_m, V_m and IC_{50}) of both *H* and *L* antioxidants, were depicted using a simplex
598 method tool to solve linear problem. Restrictions were made to the variable coded
599 values that did not allowed the set of equations consider unnatural conditions (*i.e.*,
600 lower times than 0). Additionally, optimal extraction conditions for both *H* and *L*
601 antioxidants based on all the response criteria were determined (*i.e.*, *t*, 12.1 min; *T*,
602 122.3 ºC; *Et*, 100 %; and *S/L*, 27.2 g/L), which allow to obtain the maximum extraction
603 yield of both antioxidants simultaneously.
604
605 **4. Conclusions**
606 Optimal MAE conditions for *H* and *L* antioxidants from a surplus tomato crop were
607 determined in this study. A five-level full factorial Box-Behnken design was
608 successfully implemented and RSM used for analysis. The independent variables of *t*, *T*,
609 *Et* and *S/L* had significant effects on MAE. To predict the optimal extraction conditions,
610 a second-order polynomial model assuming interactive effects was fitted to each
611 response and the regression coefficients were determined using the least-squares
612 method. Optimal MAE conditions for *H*, *L* and both antioxidants were determined
613 based on the parametric response criteria P_m, V_m and IC_{50}. Overall, MAE proved to be a
614 powerful and efficient innovative methodology to extract the tomato antioxidants. In
615 statistical terms, the high values of the adjusted coefficient of determination (R^2_{adj} >
616 0.90) and the non-significant difference between predicted and experimental values
617 demonstrated the validity of the proposed optimization model. The results also indicated

618 that the antioxidant capacity of the *H* fraction was much higher than the *L* one.
619 Additionally, a discussion on the relationship between the extraction capacity of the
620 solvent in function of its polarity and the antioxidant activity of the extracts in *H* and *L*
621 media (the so-called polarity-activity relationship) was initiated, providing useful
622 information in the study of complex natural extracts containing ingredients with
623 opposite degrees of polarity.

Figures

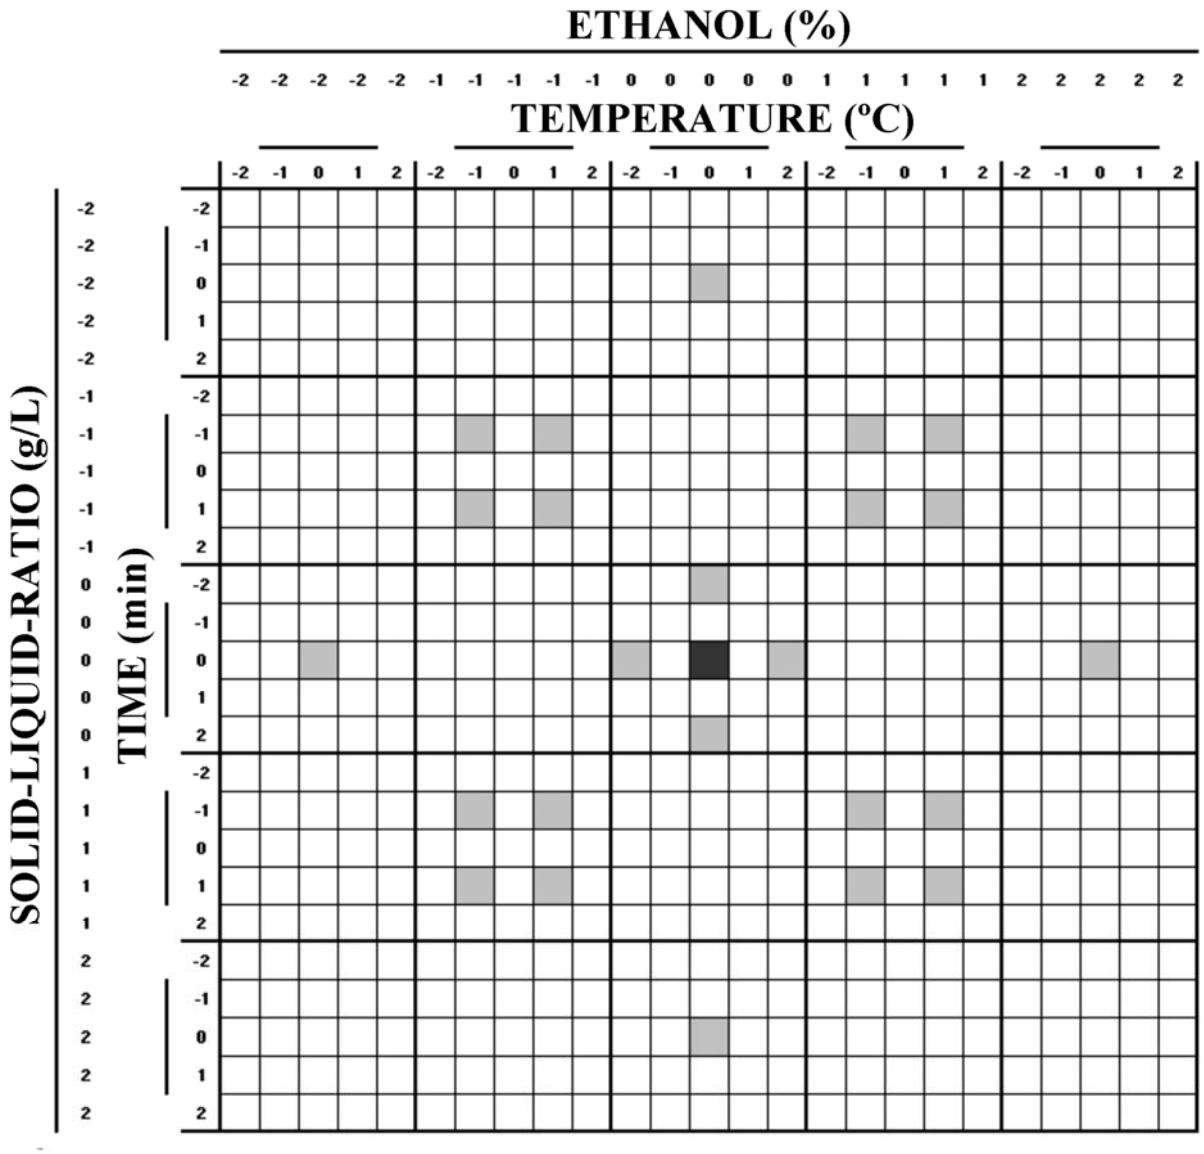

Fig. 2 - Visual representation of the applied experimental RSM design. Four independent variables (extraction time (X_1), temperature (X_2), ethanol concentration (X_3), and solid/liquid ratio (X_4)) were combined in a five-level full factorial design of 25 independent variable combinations (grey grid) and 7 replicates in the centre of the experimental domain (dark grid). Coded values (-2, -1, 0, +1, +2) are in natural values X_1 (*t, min*: 0, 5, 10, 15, 20), X_2 (*T*, ºC: 60, 90, 120, 150, 180), X_3 (*Et*, %: 0, 25, 50, 75, 100) and X_4 (*S/L*, g/L: 5, 15, 25, 35, 45).

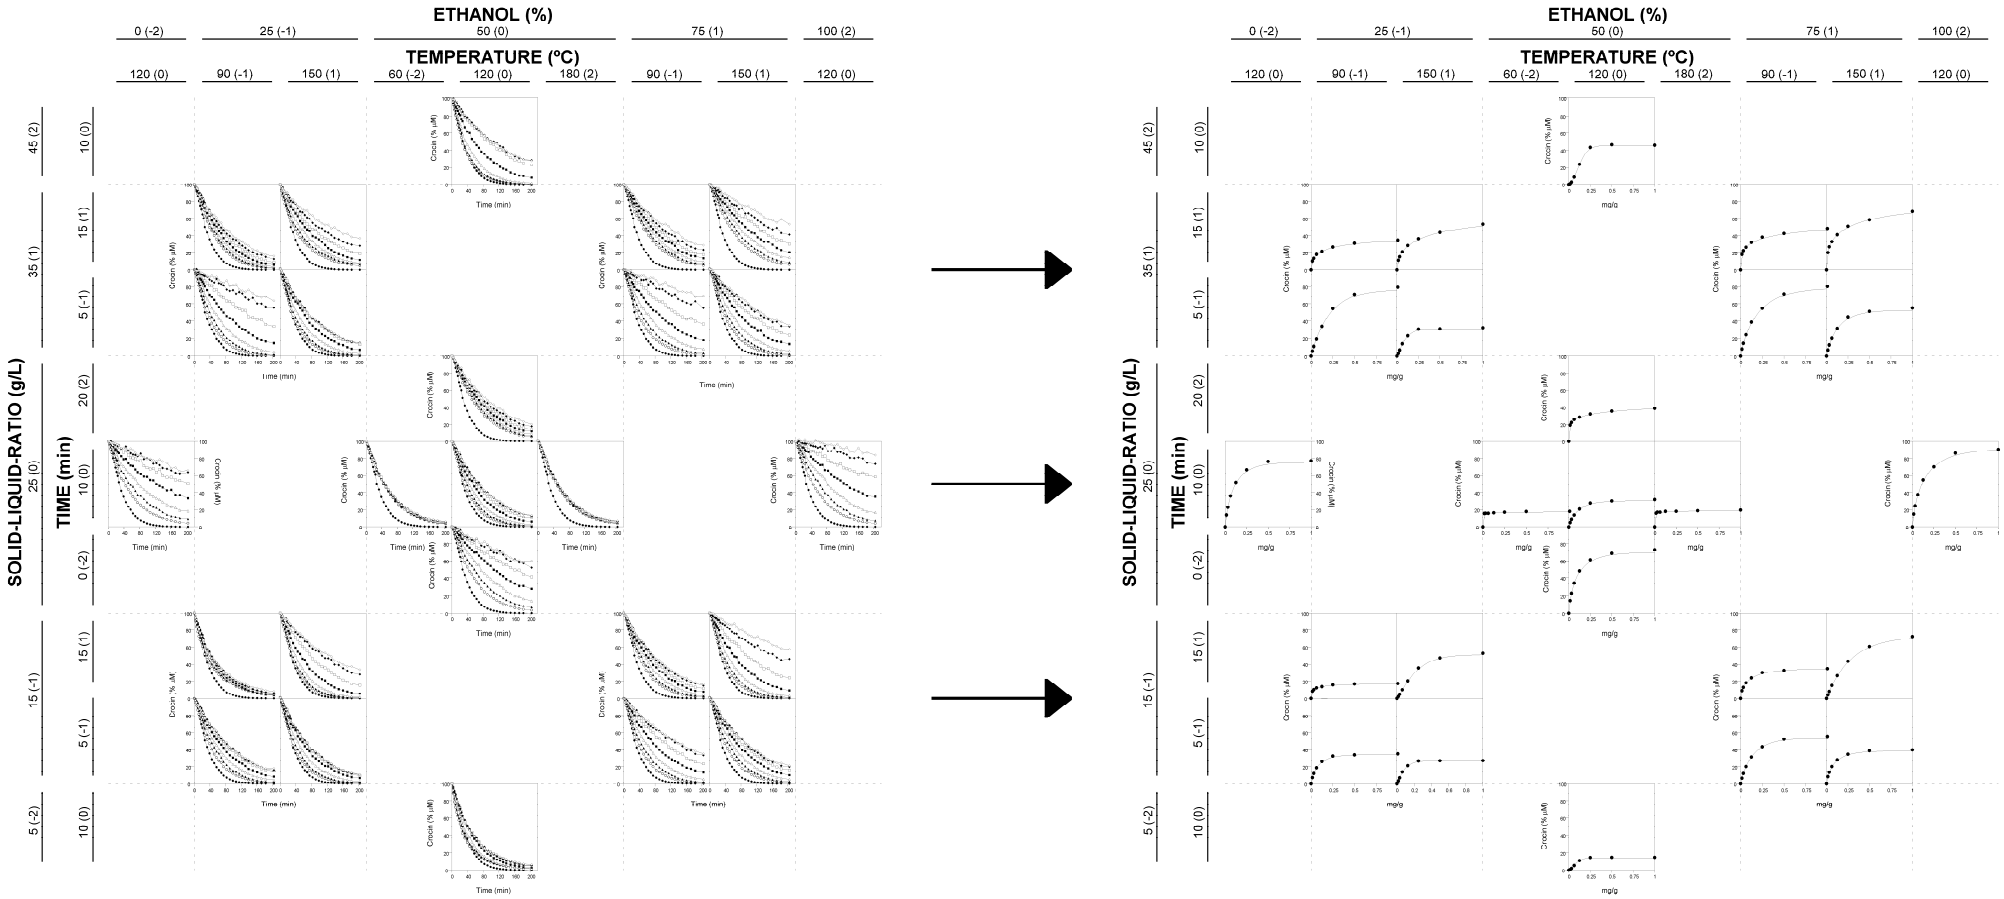

Fig. 3 - Illustration of the *H* responses obtained for the CM under the experimental RSM design presented in Fig. 2. On the left-hand side, each graph illustrates one of the 25 independent variable combinations and inside each graph can be seem the concentration-time responses of seven serial dilutions (○:1/1, ▲: 1/2, △: 1/4, ■: 1/8, □: 1/16, ◆: 1/32, ◇: 1/64) and the control (●) of the extracted material. On the right-hand side, each graph shows: 1) Dots (●), which represents the standardized $\overline{P}$ (protected percentage of Cr) values in a concentration-response format obtained by applying Eq. (2) to the concentration-time responses presented in the left-hand side; and 2) Lines (—), fitted responses to the mathematical model of Eq. (3). The obtained parametric fitting values are presented in Table 1.

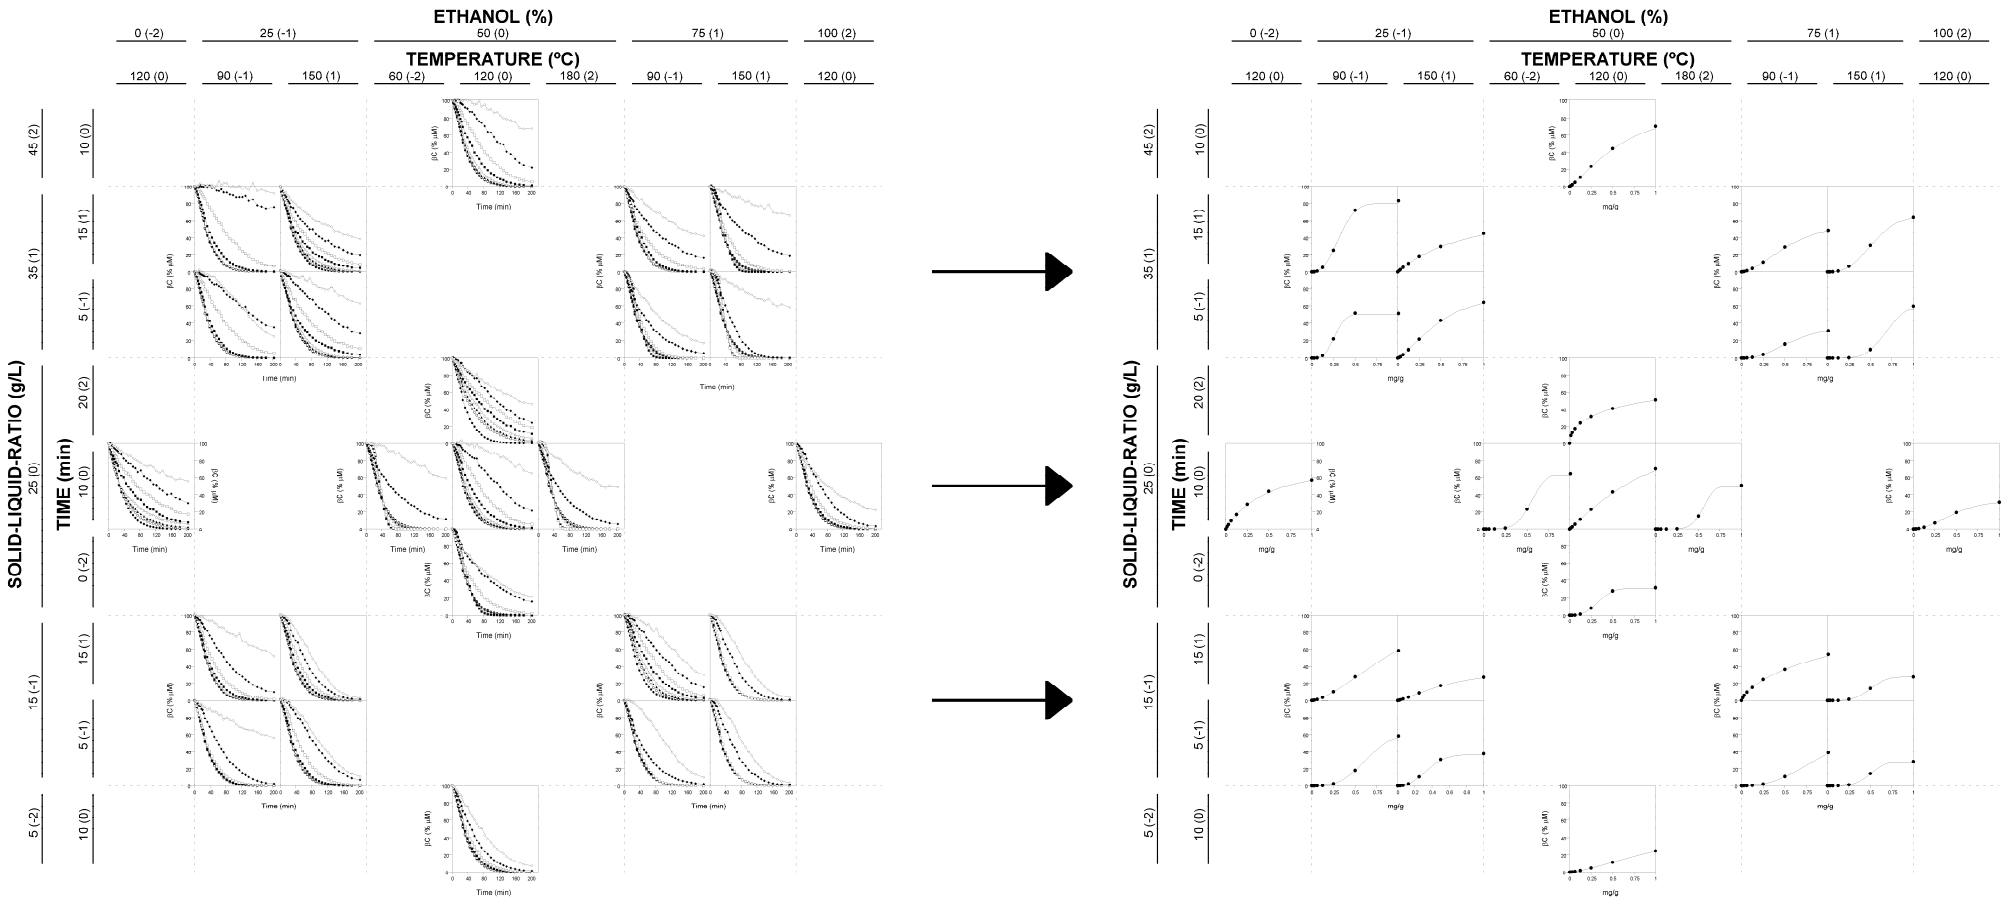

Fig. 4 - Illustration of the *L* responses obtained for the βCM under the experimental RSM design presented in Fig. 2. On the left-hand side, each graph illustrates one of the 25 independent variable combinations and inside each graph can be seem the concentration-time responses of seven serial dilutions (○:1/1, ▲: 1/2, △: 1/4, ■: 1/8, □: 1/16, ◆: 1/32, ◇: 1/64) and the control (●) of the extracted material. On the right-hand side, each graph shows: 1) Dots (●), which represents the standardized $\overline{P}$ (protected percentage of βC) values in a concentration-response format obtained by applying Eq. (2) to the concentration-time responses presented in the left-hand side; and 2) Lines (—), fitted responses to the mathematical model of Eq. (3). The obtained parametric fitting values are presented in Table 1.

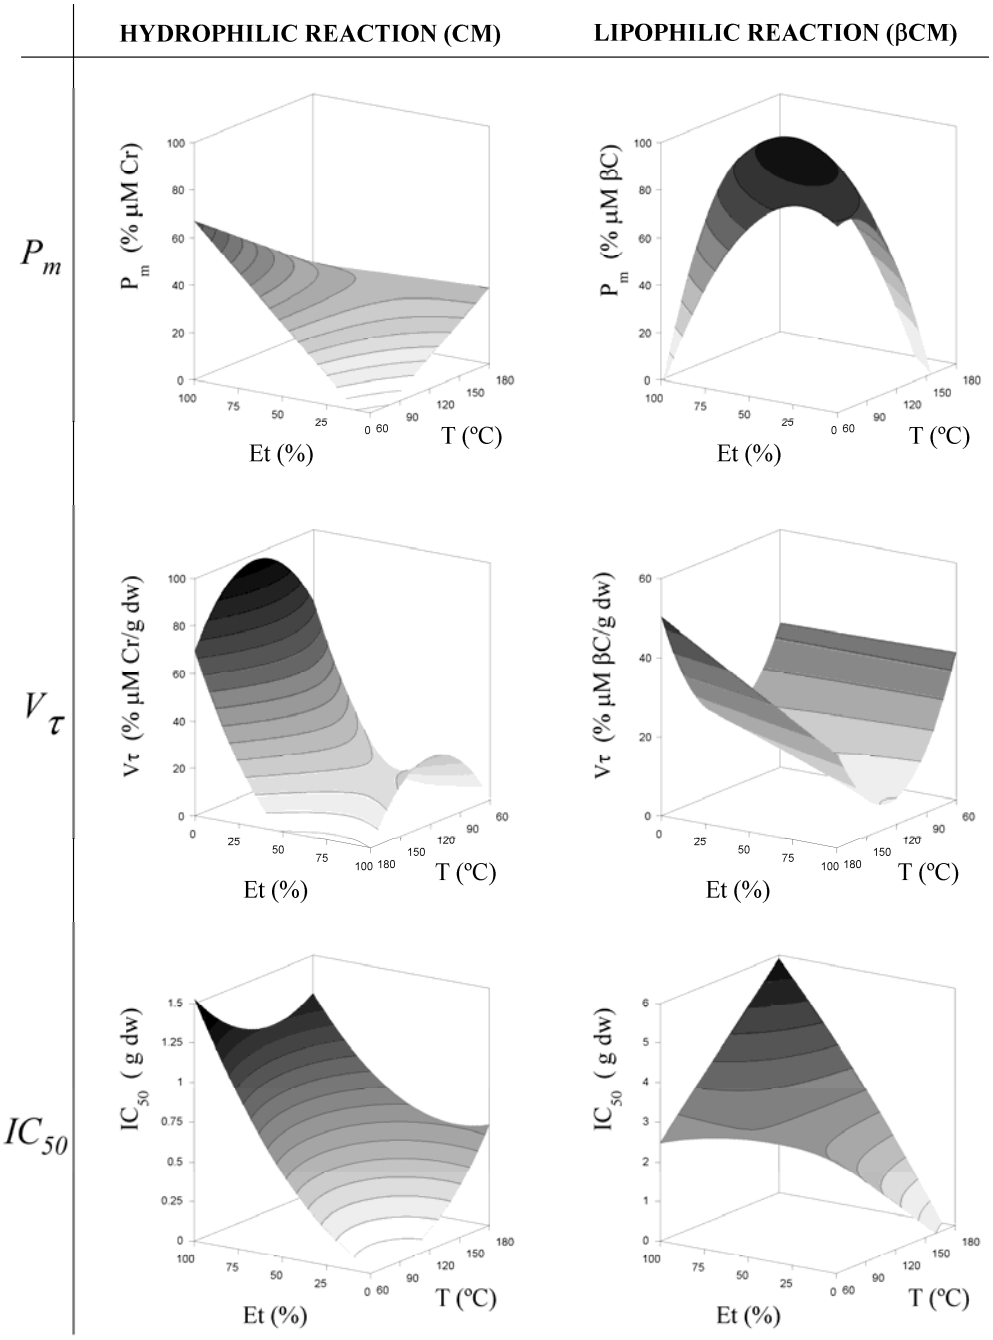

Fig. 5 - Response surfaces of the effects of ethanol concentration (*Et*) *vs* temperature (*T*) on *H* and *L* antioxidant reactions for the parametric response criteria P_m, V_m and IC_{50}. For representation purposes, the variables *t* and *S/L* were positioned at the centre of their experimental domain (*t*=10 min and *S/L*=25 g/L). The obtained parametric fitting values are presented in Table 2.

1

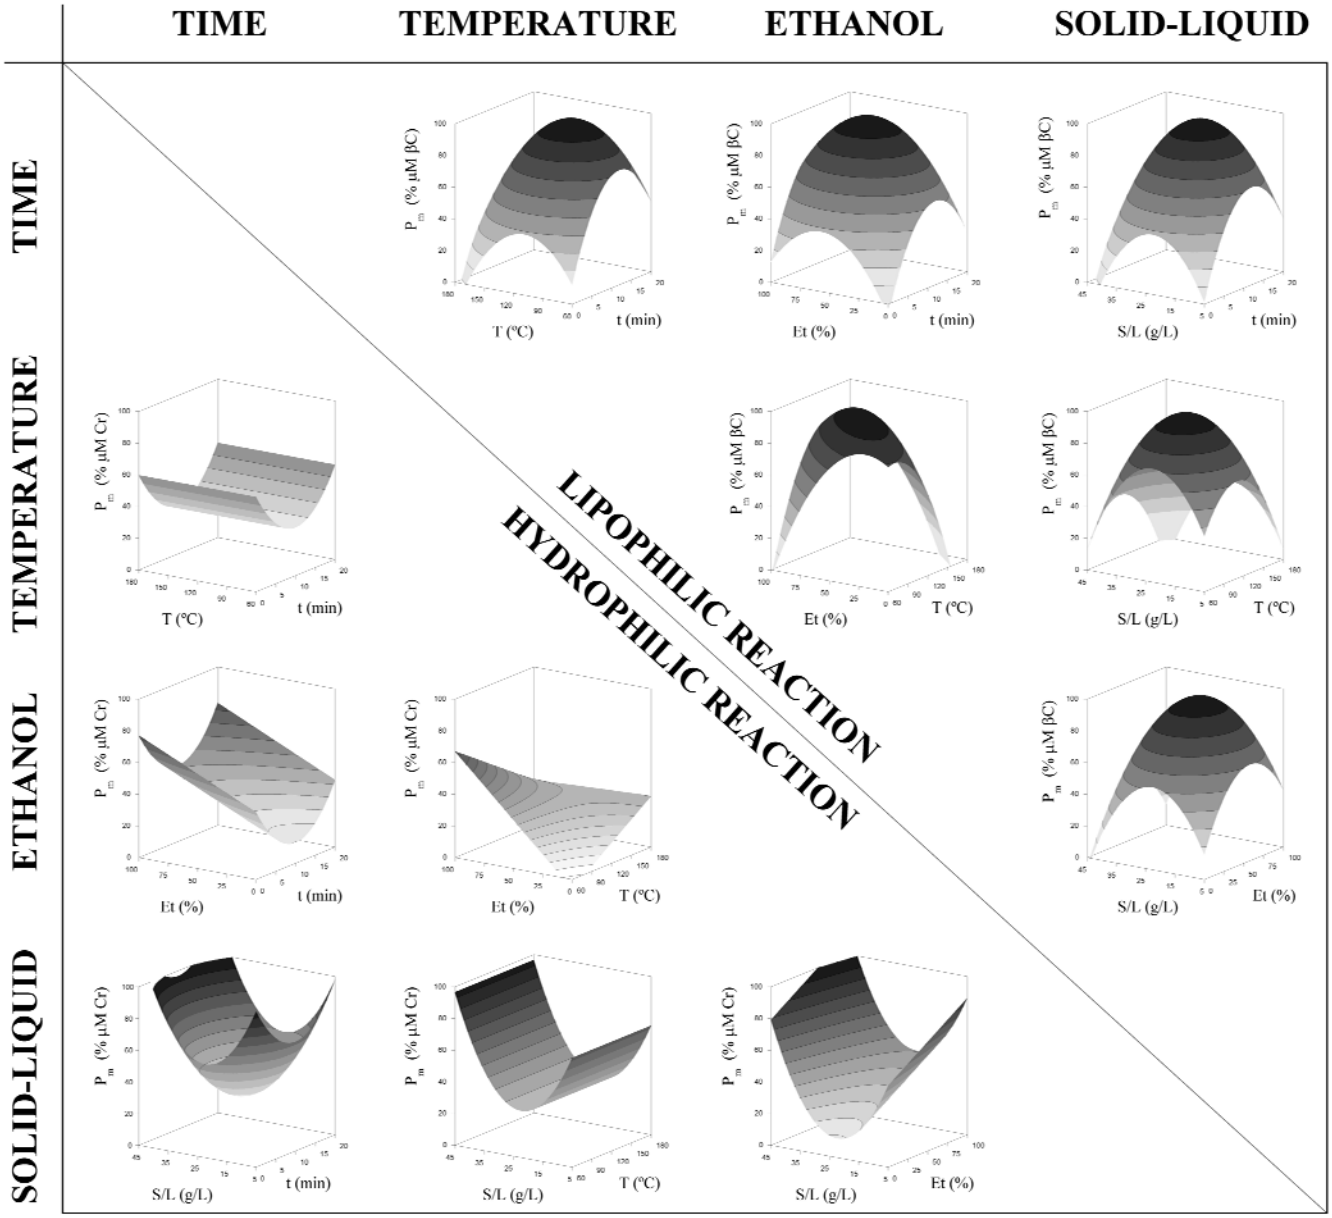

Fig. 6 - Matrix combination of the response surfaces of the *H* and *L* antioxidant reactions obtained for the parametric coefficient P_m (% µM of Cr or βC), which is organized as follows: a) in the top diagonal part is presented the response surface of the *L* reaction; and b) in the bottom diagonal part is presented the response surface of the *H* reaction. For representation purposes, the variables excluded in each 3D graph were positioned at the centre of their experimental domain (*t*=10 min; *T*=120 ºC; *Et*=50 %; and *S/L*=25 g/L). The obtained parametric fitting values are presented in Table 2.

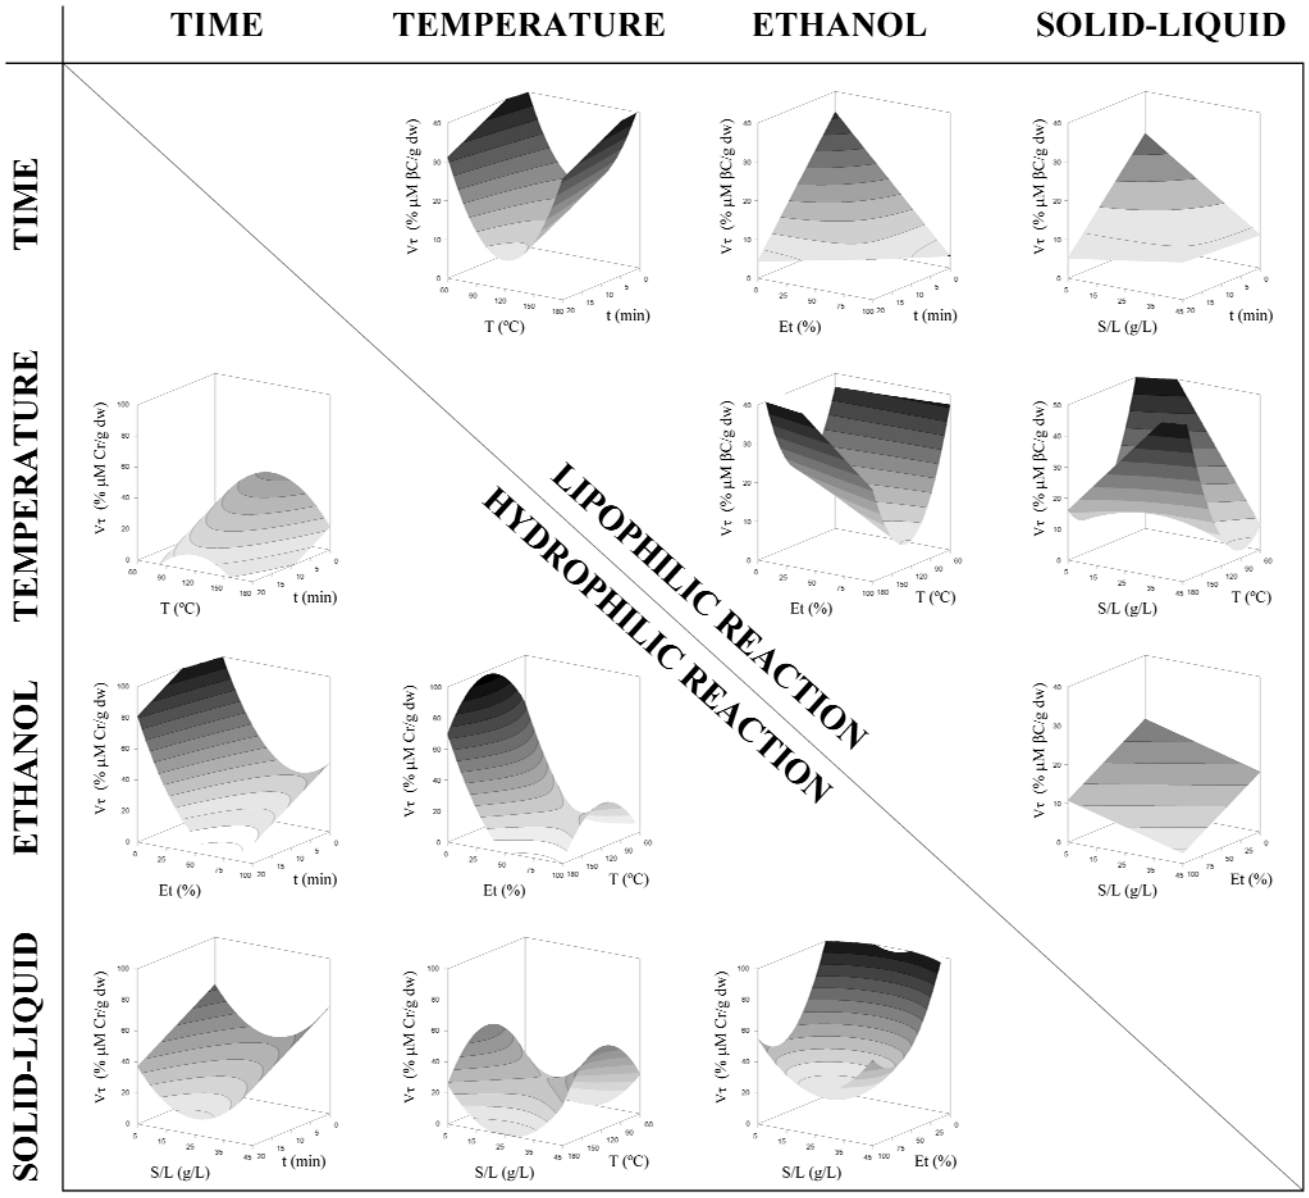

Fig. 7 - Matrix combination of the response surfaces of the *H* and *L* antioxidant reactions obtained for the parametric coefficient V_m (% µM of Cr or βC/g extract), which is organized as follows: a) in the top diagonal part is presented the response surface of the *L* reaction; and b) in the bottom diagonal part is presented the response surface of the *H* reaction. For representation purposes, the variables excluded in each 3D graph were positioned at the centre of their experimental domain (*t*=10 min; *T*=120 ºC; *Et*=50 %; and *S/L*=25 g/L). The obtained parametric fitting values are presented in Table 2.

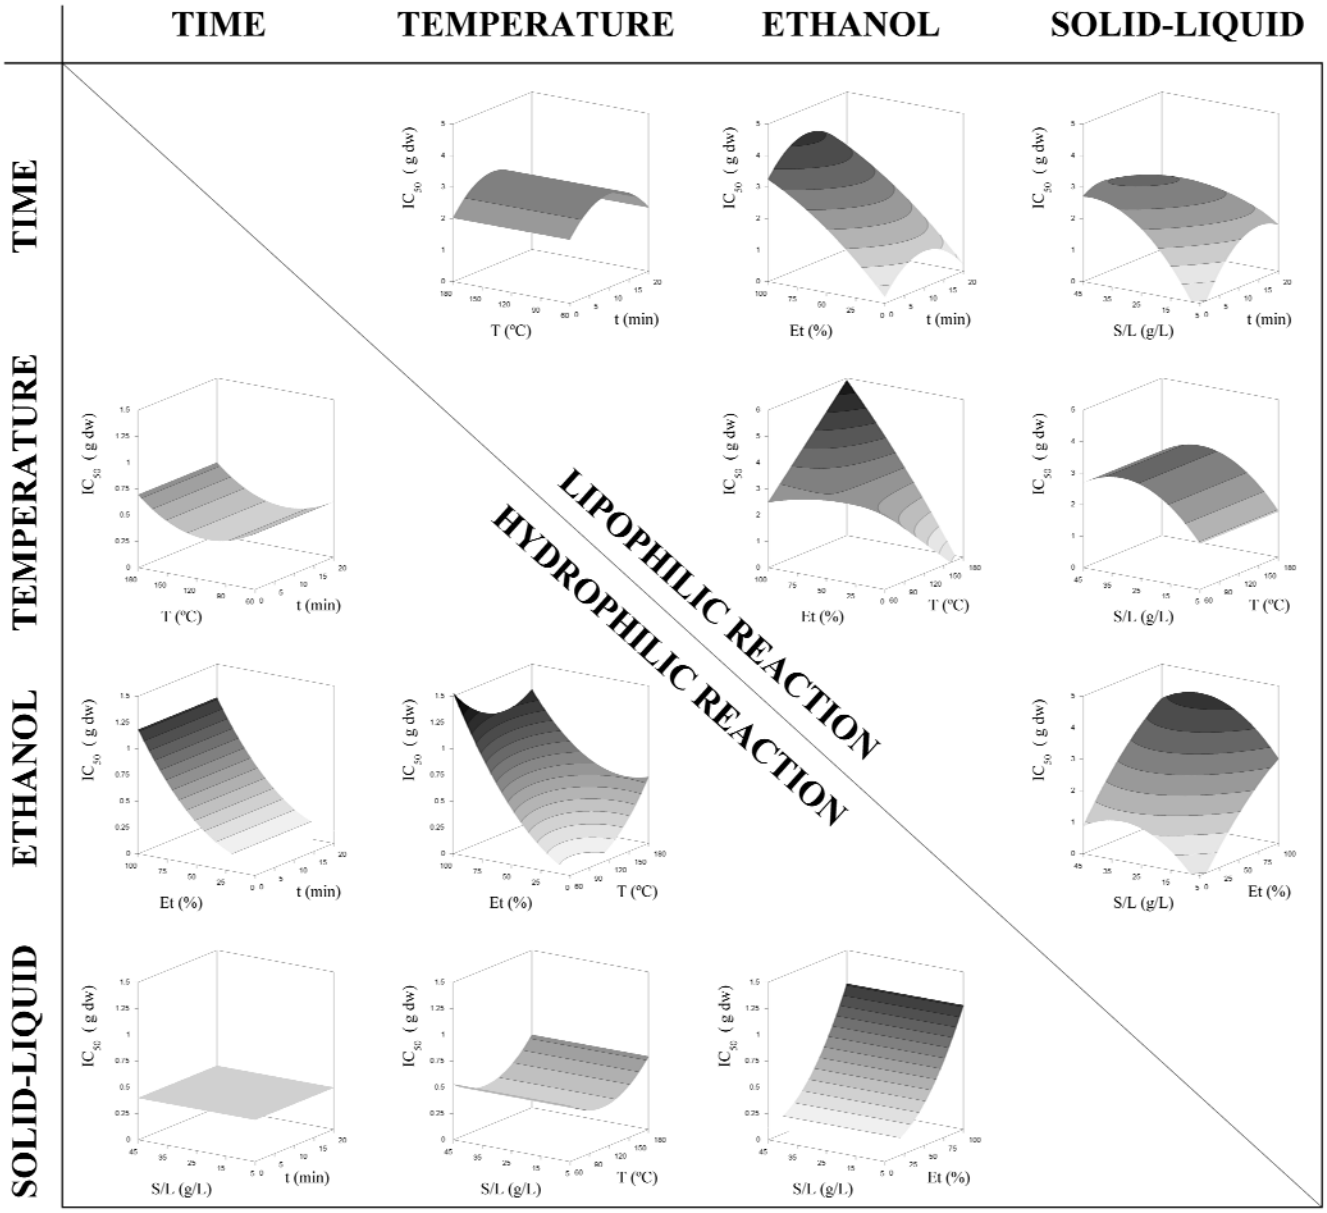

Fig. 8 - Matrix combination of the response surfaces of the *H* and *L* antioxidant reactions obtained for the parametric coefficient IC_{50} (g extract), which is organized as follows: a) in the top diagonal part is presented the response surface of the *L* reaction; and b) in the bottom diagonal part is presented the response surface of the *H* reaction. For representation purposes, the variables excluded in each 3D graph were positioned at the centre of their experimental domain (*t*=10 min; *T*=120 ºC; *Et*=50 %; and *S/L*=25 g/L). The obtained parametric fitting values are presented in Table 2.

Tables

Table 1 - Estimated numerical values of the parameters (P_m, V_m and IC_{50}) of Eqs. (3) and (4), after fitting the concentration-response values presented in the right-hand side of Fig. 3 and Fig. 4 (for CM and βCM, respectively) of the tomato extracts obtained under the experimental RSM design presented in Fig. 2.

DW		2.39	2.20	1.43	2.32	1.36	2.32

ns: no significant coefficient; **R^2**: Correlation coefficient; **R^2adj**: The adjusted coefficient of determination for the model; **MSE**: The mean squared error; **RMSE**: The root mean square of the errors; **MAPE**: The mean absolute percentage error; and **DW**: The Durbin-Watson statistic.

Table 3 - Operating conditions that maximize the extraction of *H* and *L* antioxidants from tomato and optimal response values for the parametric response criteria (P_m, V_m and IC_{50}) and antioxidant reactions (*H* or *L*). The independent variables *t*, *T*, *Et* and *S/L* are presented in natural values.

	OPTIMAL EXTRACTION CONDITIONS				**RESPONSE OPTIMUM**
	X_1: *t (min)*	X_2: *T (ºC)*	X_3: *Et (%)*	X_4: *S/L (g/L)*	
For H antioxidants					
P_m (*H*)	18.7	180.0	56.8	45.0	100 *% μM Cr*
V_m (*H*)	2.5	120.0	0.0	5.0	136.11 *% μM Cr/g extract*
IC_{50} (*H*)	14.5	90.0	44.0	17.0	0.051 *g extract*
For L antioxidants					
P_m (*L*)	13.4	93.6	44.0	21.3	100 *% μM βC*
V_m (*L*)	2.2	180.0	100.0	5.0	78.70 *% μM βC/g extract*
IC_{50} (*L*)	2.6	169.1	91.7	10.9	0.025 *g extract*
For each response criteria of both H and L antioxidants					
P_m (*H*)	15.4	127.6	93.2	33.8	100.0 *% μM Cr*
P_m (*L*)					43.4 *% μM βC*
V_m (*H*)	3.9	63.3	0.0	5.0	108.93 *% μM Cr/g extract*
V_m (*L*)					74.79 *% μM βC/g extract*
IC_{50} (*H*)	13.9	112.7	89.0	5.3	0.06 *g extract*
IC_{50} (*L*)					0.05 *g extract*
For H and L antioxidants based on all the response criteria					
P_m (*H*)					100 *% μM Cr*
V_m (*H*)	2.25	149.2	99.1	45.0	60.2 *% μM Cr/g extract*
IC_{50} (*H*)					0.09 *g extract*
P_m (*L*)					92.4 *% μM βC*
V_m (*L*)	15.4	60.0	33.0	15.0	42.9 *% μM βC/g extract*
IC_{50} (*L*)					0.38 *g extract*
For both H and L antioxidants based on all the response criteria					
P_m (*H*)					100.0 *% μM Cr*
P_m (*L*)					39.1 *% μM βC*
V_m (*H*)	12.1	122.3	100.0	27.2	46.39 *% μM Cr/g extract*
V_m (*L*)					9.64 *% μM βC/g extract*
IC_{50} (*H*)					0.47 *g extract*
IC_{50} (*L*)					0.47 *g extract*
