Abstract

Interest in microwave-induced pyrolysis has increased in recent years due to its several advantages over conventional pyrolysis. Most of these advantages are related to the presence of microplasmas in microwave heating, since the pyrolysis reactions that take place in a plasma atmosphere generally produce light molecules, such as H₂ and CO. Although the exact nature of these plasmas is as yet unknown, it is likely to be dependent on the ionization of the surrounding gases. For this reason, the influence of different carrier gases (N₂, He or no carrier gas) on microwave-induced pyrolysis was chosen as the subject of this study. It was found that microwave-induced pyrolysis can be used to obtain equally good gas compositions and yields after the reactor has been inertized, without the need for a carrier gas.

Keywords

Microwave pyrolysis, Carrier, Microplasmas, Syngas

2 **Highlights**

- 3 • The nature of the carrier gas upon syngas from microwave pyrolysis has been
- 4 studied
- 5 • Both N₂ and He yields similar gas compositions and yields
- 6 • Microwave pyrolysis without using a carrier gas is a promising alternative

1. Introduction

Microwave heating has attracted increasing attention as an energy source for pyrolysis processes over the last decade [1]. This interest stems from the advantages that microwave heating offers over conventional heating, including higher heating rates, volumetric and selective heating, shorter operation times and a quick start-stop capability [2,3]. In the specific case of pyrolysis, microwave heating has been demonstrated to produce extraordinary gas yields, especially, of syngas [1,4,5]. This has promoted interest in microwave-induced pyrolysis (MIP) as a means of converting organic feedstock in biorefineries into energy, fuels or materials [6,7]. Apart from parameters, such as the operating conditions or the type of feedstock used in the process [1,8,9], the main reason for this high productivity seems to be the presence of microplasmas during microwave heating [2,10].

These plasmas are *hot spots* that are confined to a very tiny space and last only a fraction of a second. The temperature at these points is significantly higher than the mean temperature of the rest of the material and high enough to cause the ionization of the surrounding molecules. It is thought that these plasmas can influence the yields of the different fractions (solid, liquid and gas) obtained in the pyrolysis as well as the composition of the gas produced [4]. These localized higher temperatures facilitate the extraction of volatiles from the matter. In addition, the plasmas enhance heterogeneous reactions (such as thermal cracking or the reforming of hydrocarbons) [2,11], thus modifying the composition of the evolved volatiles. Although the nature of these plasmas is unknown, there is some evidence to suggest that it is dependent on the gaseous molecules that are being ionized within the plasma. For example, the presence

of high proportions of H₂ during the microwave-assisted dry reforming of coke oven gas, has allowed higher plasma temperatures than in the dry reforming of methane [12]. For this reason the carrier gas used in the pyrolysis can affect the microplasmas and influence the distribution of the product obtained in the process. Several works have been focused on the influence of the carrier gas on the pyrolysis in physical terms (i.e., contact time or dilution). However, there is a lack of studies on the influence of this parameter upon the microplasmas.

The objective of the present study is to fill this gap by undertaking an analysis of the yields and gas compositions obtained with N₂ and He as carrier gases and, in some cases, in the absence of a carrier gas in order to determine their influence on the process of microwave-induced pyrolysis.

2. Material and methods

2.1 Waste used in pyrolysis

The sample selected for this study was a dried and cleaned organic fraction from a municipal solid waste, supplied by BEFESA *Gestión de Residuos Industriales* S. L. (Seville, Spain). Details of the characterisation of this sample can be found elsewhere [13]. The study of the influence of the carrier gas on pyrolysis was carried out using nitrogen, helium and no carrier gas.

2.2 Pyrolysis techniques and characterization of gases

Microwave-induced pyrolysis was performed at 400 and 800 °C using the system shown in Fig. 1a. This system consists of a microwave magnetron with a maximum output power of 2 kW operating at 2450 MHz and a single mode cavity where the sample is

placed (approximately 4 g of waste), coupled to a condenser and a gas collecting station (Fig. 1b). The temperature was controlled by means of an optical pyrometer. The gas collector is fitted with a pump by means of which the resulting pyrolysis gas is fed into a gas cylinder. A series of valves are so tuned as to prevent a vacuum from forming inside the reactor while the evolved gas is being compressed inside the station by means of a looping circuit. The valve-tuning procedure which is illustrated in Fig. 2 is as follows:

- a) Cylinder purge. In order to ensure the removal of all previous pyrolysis gases from inside the cylinder, the pump is used to produce a vacuum inside the cylinder.
- b) Cylinder inertisation. A carrier gas (N_2 or He) is fed into the cylinder so as to ensure a clean atmosphere inside.

Both steps are repeated three times. Once the cylinder has been cleaned and is in a state of vacuum, the pyrolysis process is initiated and the gas passes through the system until it reaches the cylinder where it is stored (step c in Fig. 2).

To study the influence of the carrier gas, the reactor was initially purged with N_2 or He for 30 minutes at a flow rate of $50 \text{ mL}_{\text{STP}} \text{ min}^{-1}$. When no carrier gas was used, the purge was carried out with N_2 . The flow rate was then reduced to $10 \text{ mL}_{\text{STP}} \text{ min}^{-1}$ (or switched off in the event of no carrier gas being used) and the microwave irradiation was switched on during 1h. The reflected power was regulated by means of tuning screws until it reached zero. However, owing to the poor capacity of organic wastes to absorb microwaves, it was necessary to use a microwave receptor to induce the

pyrolysis. The char obtained from previous pyrolysis was used for this purpose, since it is a product of the process itself, does not contain any strange material that might influence the composition of the fractions and is known to facilitate rapid heating and to achieve the necessary pyrolysis temperature in a short time [4,6,13]. For this study, a receptor-to-residue mass ratio of 0.3:1 was selected. The volatiles evolved during the pyrolysis were forced to pass through a condensing system (cooled by a cryogenic solution of water and NaCl) where the condensable compounds were removed from the gaseous fraction. The gaseous fraction in the cylinder was then analysed by means of a Varian-CP3800 gas chromatograph equipped with a TCD detector and two columns connected in series. The first column was 80/100 Hayesep Q (2 m x 1/8 in. x 2mm) and the second column was a 80/100 Molesieve 13X (1.5 m x 1/8 in. x 2 mm). The second column was bypassed by a six-port valve for the analysis of the CO₂ and hydrocarbons. The carrier gas flow (He) was 30 mL/min. The initial oven temperature was set at 40 °C, which was maintained for 1.2 min. It was then programmed to rise from 40 to 65 °C at 50 °C/min with an isothermic step of 3.7 min. The temperature was then lowered from 65 to 55 °C at 20 °C/min and held for 3.1 min. The injector and detector temperatures were fixed at 150 °C. The TCD was calibrated using a standard gas mixture. Both the reactor and the condensing system were weighed before and after the pyrolysis experiments to measure of the solid and liquid yields. The gas yield was determined by difference. Each experiment was performed by duplicate and the results showed repeatability.

For purposes of comparing the influence of different carrier gas in a different heating mode, conventional pyrolysis was performed in an electric furnace (EF) using the same quartz reactor, temperatures, residence time and oils collector as in MIP in order to

determine whether the nature of the carrier gas affected the microplasmas generated during MIP, and in turn the fraction yields obtained from the pyrolysis. Both experimental devices are described elsewhere [4].

3. Results and Discussion

The effect of using different carrier gases during pyrolysis on the gas yield is illustrated in Fig. 3. As can be seen, there are almost no differences in the yields obtained with the different carrier gases (on a carrier gas free basis). The use of He enhances the gas yield slightly, although this enhancement cannot be strictly attributed to the microplasma phenomenon, since there is also a slight increase in the case of conventional pyrolysis at 800 °C, where no microplasmas are generated. Furthermore, MIP increases the gas yield more than conventional pyrolysis, regardless of whether N₂ or He is used, as has been reported previously [4,8].

The carrier gas also influences the gas composition (Table 1). In the case of MIP, N₂ and He produce nearly the same composition with a syngas (H₂+CO) concentration at 400 °C of ca. 80 vol.%. Thus, the generated microplasmas from N₂ and He must be of the same nature. Nevertheless, if no carrier gas is used, the syngas proportion is less than that produced (ca. 69 vol.%), the generation of CO₂ and CH₄ in this case being favoured. Consequently, it is thought that the use of a carrier gas during MIP may favour gasification and methane cracking reactions (reactions 1 and 2), by allowing a better contact between the solid and gas phases. At a higher temperature, 800 °C, MIP provides nearly the same composition regardless of whether a carrier gas is used or not.

2

3 In conventional heating, the absence of a carrier gas favours the generation of CO_2 ,
4 aromatics and high hydrocarbons ($> \text{C}_2$). This gives rise to a low-quality gas fraction in
5 terms of syngas production, especially at 400 °C, evidencing the superiority of MIP,
6 since at 400 °C microwaves reduce the high hydrocarbon content from 52.36 vol.% to
7 virtually 0 vol.%. For this reason, in the case of conventional pyrolysis, it is important
8 to use a carrier gas at low temperatures. However, the differences with conventional
9 pyrolysis at high temperature (800 °C) whether a carrier gas is used or not are not so
10 great, the gas composition being nearly the same with N_2 and He, though without a
11 carrier gas, the syngas concentration diminishes in favour of CO_2 and heavy
12 hydrocarbons. This can be attributed to a smaller conversion of tar and gases to syngas,
13 perhaps due to a poorer contact between the solid and gas phases.

14

15 Besides the composition of the gas fraction, it is also necessary to consider the energy
16 content in terms of the energy of the gas obtained both per gram of waste pyrolyzed and
17 per gram of gas, which depend on the pyrolysis yields and the composition of the gas
18 fraction, as shown in Table 2. The largest differences correspond to conventional
19 pyrolysis at low temperature. In this case the energy content per gram of gas is the
20 maximum value obtained. This is due to the large proportion of heavy hydrocarbons,
21 which are much more energetic than CH_4 , H_2 or C_2 present in the gaseous fractions
22 obtained under other experimental conditions. The large proportions of high
23 hydrocarbons may be due to the longer residence time, as has been recently reported in
24 the case of the pyrolysis of other wastes [14,15]. However, at higher temperatures, the
25 differences are not as great. The energy extracted from the waste is almost the same and

the energy contents of the gases are similar, the maximum value being reached in the experiment with no carrier gas.

When microwave heating is used more energy is extracted from the waste than under conventional heating. Both at low and high temperatures the energy extracted from the waste and the energy content of the gas are very similar regardless of the carrier gas used. When no carrier gas is used, the values are slightly lower than with N₂ or He.

4. Conclusions

The use of different carriers affects the yields of the fractions obtained during the pyrolysis of organic residues only slightly. In the case of conventional pyrolysis, the absence of a carrier gas promotes the generation of CO₂, aromatics and heavy hydrocarbons, yielding a gas fraction of low quality. Nevertheless, in microwave pyrolysis, and especially at high temperature, no significant differences in the gas composition were observed when using different carriers, though a small increase in the gas yield was obtained with helium as carrier gas. The results of this point the way to the implementation of microwave pyrolysis without the need for a carrier gas.
