### **Abstract**

Gold nanoparticles (AuNPs) are present in many man-made products and cosmetics, and are also used by the food and medical industries. Tight regulations regarding the use of mammalian animals for product testing can hamper the study of the specific interactions between engineered nanoparticles and biological systems. Invertebrate models, such as the nematode *Caenorhabditis elegans* (*C. elegans*), can offer alternative approaches during the early phases of nanoparticle discovery.

Here, we thoroughly evaluated the biodistribution of 11-nm and 150-nm citrate-capped AuNPs in the model organism *C. elegans* at multiple scales, moving from micrometric to nanometric resolution and from the organismal to cellular level. We confirmed that the nanoparticles were not able to cross the intestinal and dermal barriers. We investigated the effect of AuNPs on the survival and reproductive performance of *C. elegans*, and correlated these effects with the uptake of AuNPs in terms of their number, surface area, and metal mass. In general, exposure to 11-nm AuNPs resulted in a higher toxicity than the larger 150-nm AuNPs. NP aggregation inside *C. elegans* was determined using absorbance microspectroscopy, which allowed the plasmonic properties of AuNPs to be correlated with their confinement inside the intestinal lumen, where anatomical traits, acidic pH and the presence of biomolecules play an essential role on NP aggregation. Finally, quantitative PCR of selected molecular markers indicated that exposure to AuNPs did not significantly affect

endocytosis and intestinal barrier integrity.

### **Statement of significance**

This work highlights how the simple, yet information-rich, animal model *C. elegans* is ideally suited for preliminary screening of nanoparticles or chemicals mitigating most of the difficulties associated with mammalian animal models, namely the ethical issues, the high cost, and time constraints. This is of particular relevance to the cosmetic, food, and pharmaceutical industries, who all have to justify the use of animals, especially during the discovery, development and initial screening phases. This work provides a detailed and thorough analysis of 11-nm and 150-nm AuNPs at multiple levels of organization (the whole organism, organs, tissues, cells and molecules).

**Keywords:** biological interactions, *Caenorhabditis elegans*, digestive system, enterocytes, endocytosis, gold nanoparticles.

## Introduction

Many of the products used in our daily life contain nanoparticles, gold nanoparticles (AuNPs) in facial creams,[1] silver nanoparticles in preservatives,[2] or zinc oxide nanoparticles and titanium dioxide nanoparticles in colorants and sunscreens [3]. For example, colloidal AuNPs hold great promise in cosmetics and as therapeutic and diagnostic agents due to their inertness (which limits their toxicity to cells) and their unique optical and photothermal properties. The latter can be controlled and tuned by changing the size, shape, and surface functionalization of AuNPs.[4, 5]

AuNPs have been selected by the Working Party on Manufactured Nanomaterials of the Organization for Economic Cooperation and Development (OECD) as an example of manufactured nanomaterials which are either in commercialization or likely to enter the market in the near future.[6] Indeed, some AuNPs formulations have already been proposed as novel tools for *in vitro* and *in vivo* molecular imaging and drug delivery.[7] AuNPs have, for example, attracted interest as carriers to enhance the oral absorption of drugs and vaccines that are either poorly absorbed or are susceptible to gastrointestinal degradation.[8] However, to our knowledge, only AuNPs used for local heat generation in the plasmonic photothermal therapy of atherosclerosis and cancer have, to date, reached clinical stage (ClinicalTrials.gov Identifiers NCT01270139, NCT01679470, NCT00848042, NCT00436410).[9] In addition, AuNPs are present in day to day products such as anti-ageing creams and masks, toothpastes, and are even marketed as food supplements according to the Consumer Products Inventory, which is compiled by the Project on Emerging Nanotechnologies.[10] However, the regulations on nanoparticles are being tightened and the use of animal-free alternatives to evaluate new materials is being actively promoted. For instance, in March 2013, EU regulations on Cosmetics and Household Products banned the use of animals to assess the safety of these products. The North American Food and Drug Administration (FDA) also supports the development and use of alternatives to animal testing to assess the safety of cosmetic products.[11] Hence, there is a pressing need to develop new platforms and approaches to evaluate AuNPs-containing products in particular to hasten the early stages of safe nanoparticle development in the cosmetic, food, and pharmaceutical industries.

In this context, animal models such as *Caenorhabditis elegans*, *Drosophila melanogaster* or *Danio rerio* allow scientists to obtain primary data on engineered

nanomaterials in a simple biological experimental system, and in doing so face less strict regulations and ethical issues compared to research conducted with mammals. These model organisms are compatible with high-throughput screens, even microfluidic technologies, which in turn accelerate the path to the market.[12, 13] *C. elegans* is a worm which exhibits 60-80% genome homology with humans and shares a multitude of biological traits in terms of physiology, anatomy, and metabolism (Figure 1).[14, 15] The use of these 1-mm long animals, which naturally live in decaying organic matter in the soil, allow a cost-effective initial biological assessment of nanomaterials within chemical laboratories.[16] In addition, their transparency, small size, prolific and short lifecycle, and few requirements of maintenance facilitate the study of the interaction between nanomaterials and a multicellular organism.[16] The external part of the worm, the cuticle, can be used as a skin model given that its function and composition is analogous to human skin (Figure 1A).[14, 17, 18] The *C. elegans* intestine also shares a similar cellular architecture with higher animals with respect to cell polarity of the intestinal cells (enterocytes) including the presence of apical and basolateral domains, cell junctions, and the presence of microvilli forming the brush border (Figure 1B). Setting aside some differences in the composition, both mammals and *C. elegans* encompass a peritrophic-like layer that protects the microvillar surface of the gut.[14, 19-23] Furthermore, the mechanisms of transport of biomolecules through the biological barriers are highly conserved.[24-26] Therefore, *C. elegans* offers promising features and valuable tools to evaluate the delivery of topical and oral nanomaterials before moving to more complex model organisms.[16, 27] *C. elegans* can be used to track NPs through different biological barriers (dermal and intestinal) and multiple levels of organization (the whole organism, organs, tissues, cells and molecules).

Here, we report how advanced optical techniques such as two-photon luminescence microscopy (TPLM)[28], together with an array of materials-science characterization techniques and state-of-the-art electron microscopy protocols[29] can be applied to study and quantify the nano/bio interaction between monodisperse small and large citrate-coated AuNPs in *C. elegans*. The biodistribution of AuNPs inside the worm was evaluated by microscopy at multiple scales, moving from micrometric to nanometric resolution and from organs to cells. These analyses were further complemented by investigating the effect of AuNPs on the survival and reproductive performance of *C. elegans*, which were correlated with the uptake of AuNPs. We determined NP status inside *C. elegans* using absorbance microspectroscopy and related the plasmonic

properties of AuNPs with NP confinement in different anatomical areas within *C. elegans*. Finally, we selected several transcriptional markers to study whether AuNP exposure affects endocytosis and intestinal barrier integrity.

## **Methods**

### ***Materials***

*Caenorhabditis elegans* Bristol strain N2 and *Escherichia coli* OP50 were obtained from the *Caenorhabditis* Genetic Center (CGC) stock collection, University of Minnesota, St. Paul, MN, USA. Peptone, yeast extract, bacteriological agar and tryptone were purchased from Conda Lab. All other reagents were bought from Sigma-Aldrich, if not stated otherwise.

### ***Nanoparticle synthesis***

The 11-nm citrate-coated AuNPs were synthesized by the Frens Turkevich synthesis, as described previously.[30, 31] 2 mL of an aqueous solution of trisodium citrate ( $\text{Na}_3\text{C}$ , 38.8 mM) were added to 20 mL of gold chloride ( $\text{HAuCl}_4 \cdot 3\text{H}_2\text{O}$ , 1 mM) at 100 °C under stirring. The solution was kept at 100 °C for 10 min or until it turned deep red.

The 150-nm citrate-coated AuNPs were synthesized by seeded growth of 11-nm AuNPs. Two intermediate size steps were required (32 and 75 nm), as described previously.[32]

### ***NP characterization***

#### ***Dynamic light scattering***

Dynamic light scattering (DLS) and zeta potential measurements were performed with a Zetasizer Nano ZS (Malvern) with a He/Ne 633 nm laser at 25 °C. For each sample, Dynamic light scattering (DLS) and zeta potential measurements were performed with a Zetasizer Nano ZS (Malvern) with a He/Ne 633 nm laser at 25 °C. Au-NP dispersions (100 µg/ml in MilliQ water) were sonicated for 5 min before the measurement. For each sample, three independent measurements were performed.

#### ***Transmission electron microscopy***

Au-NP dispersions (100 µg/ml in MilliQ water) were sonicated for 5 min, then 15 µl were placed on a copper grid. The copper grid was blotted with a filter paper and complete evaporation was allowed at room temperature. Au-NPs were imaged with a JEOL JEM-1210 electron microscope at an operating voltage of 120 kV. About 200

different particles were computed to depict the size distribution and the mean size of AuNPs.

#### *UV-Vis spectroscopy*

A dispersion containing AuNPs in MilliQ water at 100 µg/ml was sonicated for 10 min in an ultrasound bath. Quartz cuvettes were employed in the measurements. UV-Vis spectra from 400 to 800 nm were acquired using a Varian Cary 5000 UV-Vis-NIR spectrophotometer. MilliQ water was used as blank to acquire the baseline spectra.

#### ***Exposure of C. elegans to AuNPs***

##### *Worm growth and exposure*

Nematodes were grown on nematode growth medium (NGM) and fed *Escherichia coli* OP50 according to the standard protocol at 20 °C.[33] Each plate contained 1000~2000 animals. Synchronized young adult specimens (1-day adults) were treated with 100 µg Au/mL for 24 h in MilliQ water in 24-well plates, per triplicate, in a final volume of 0.5 ml/well.

##### *AuNPs uptake*

~2000 exposed worms were thoroughly washed 4 times with fresh MilliQ water, then pelleted in a polycarbonate capsule by centrifugation (1 min at 1300 rcf) and dried overnight at 60 °C. The sample was digested with 0.5 ml aqua regia at 150 °C, and digestions blanks were performed in parallel. Finally, the volume was adjusted to 10 mL. The gold content of the resulting solution was determined in duplicate using inductively coupled mass plasma spectrometry with an Agilent 7500ce spectrometer. The conditions of ICP-MS were: Radiofrequency 1500 W, Plasma gas 15 L/min, Nebulizer 1.06 L/min, Mode no gas, 3 replicates by injection. Gold standards of 0.5, 10, 50, 100 and 200 parts per billion (ppb) were used, and 10 ppb was used as internal standard.

##### *Zeta potential measurements*

~25 synchronized young adult *C. elegans* were introduced in a Zeta potential cuvette filled with MilliQ water by picking them individually from NGM plates under the microscope. The measurements were performed with a Zetasizer Nano ZS (Malvern) with a He/Ne 633 nm laser at 25 °C. For each sample, three independent measurements were performed.

### *Scanning electron microscopy–energy-dispersive X-ray spectroscopy analysis*

Treated worms were fixed with 4% paraformaldehyde in MilliQ water for 2 h at room temperature, then washed three times with MilliQ water, and concentrated to 100  $\mu$ L by centrifugation (1 min at 1300 rcf). A sample (20  $\mu$ L) was transferred to a piece of carbon tape placed on an aluminium stub, and dried at room temperature. SEM-EDX analyses were carried out with a scanning electron microscope (QUANTA FEI 200 FEG-ESEM) equipped with an energy-dispersive X-ray (EDX) system. SEM was used under low-vacuum conditions, an acceleration voltage of 10 kV, and an electron beam spot of 3.0.

### *Biodistribution assay*

Treated worms were fixed with 4% paraformaldehyde in MilliQ water for 2 h at room temperature, then washed three times with MilliQ water, mounted on a glass slide with aqueous mounting media (Fluoromount®) and observed under the microscope. A Zeiss Axio Observer Optical Microscope in transmission mode was used to detect visible accumulation of AuNPs inside treated *C. elegans*.

### *Two-photon luminescence microscopy*

A TPLM based on a commercial Leica TCS SP5 confocal system, coupled to a MIRA 900F Ti:Sa laser source (Coherent), was used to acquire the two-photon luminescence of AuNPs inside *C. elegans*. The femtosecond laser beam was tuned in the near infrared ( $\lambda=800$  nm) and focused onto the sample by means of a microscope objective (HCX PL APO 10x/0.40 CS). The epi-collected luminescence signal was acquired in the 400–700 nm range with a hybrid detector (HyDs, Leica). Each image was taken in a 1024 $\times$ 1024 pixel format, and a scanning speed of 200 Hz. Z-stacks were collected in 6.5  $\mu$ m step size and processed using Image J software. Average power in the sample plane was measured to be 12 mW. Under these experimental conditions, endogenous two-photon autofluorescence of the worms was weak and negligible compared to the strong two-photon luminescence of Au-NPs (Video S3).

### *Absorbance microspectroscopy*

*C. elegans* were mounted as described above, visualised using an Olympus BX51 microscope and spatially resolved absorbance spectroscopy was performed by fiber-coupling the signal to a spectrometer (Shamrock SR-303i-B with Andor Solis camera: iDus DV401A-BV). The sample, illuminated in bright field geometry, was imaged at

the entrance of the optical fiber to reduce the collection area to a 10- $\mu$ m spot size. Spectra were background subtracted against and normalized with a reference spectrum (the glass slide). The spectra of ten worms per condition were acquired using 1000 s accumulation per triplicate.

#### *Toxicological assays*

We assessed survival (lethal endpoint) and brood size (sub-lethal endpoint). In the survival assay, animals were treated in 100  $\mu$ L MilliQ water (controls) or 100  $\mu$ g Au/mL (treated worms) in 96-well plates for 24 h. The assay was performed in triplicate. The plates were tapped and the worms that moved were counted as alive. Each well contained  $9\pm 3$  young adult worms. To study the brood size, individual untreated or treated young adult worms were transferred to a NGM plate seeded with an OP50 lawn at 20 °C. The number of progeny was scored after 72 h of food resumption. Results are expressed as percentage brood size in respect to the untreated (control) worms. The reprotoxicity assay was performed in triplicate.

#### *Excretion of AuNPs*

After treatment for 24 h, 6~7 worms were transferred to an NGM plate with *E. coli* OP50. Excretion of the internalized AuNPs was monitored under the light microscope up to 12 h after food resumption, based on the pink and blue color of the 11-nm Au-NPs and 150-nm Au-NPs, respectively.

#### *Correlative light electron microscopy (CLEM)*

The cellular localization of AuNPs in *C. elegans* was investigated by using correlated light and electron microscopy (CLEM). Control and treated animals were fixed by high-pressure freezing, flat-embedded in resin, and sectioned following a targeted ultra-microtomy protocol, as described previously.[29] Imaging analysis was performed with a PHILIPs CM 120 transmission electron microscope.

#### *High angle annular dark field scanning transmission electron microscopy (HAADF STEM)*

The prepared cross-sections of *C. elegans* were also visualized by means of HAADF STEM using the Magellan XHR SEM 400L at 20 kV in STEM mode, at a working distance of 4.2 mm and a current of 0.10 nA.

### *Quantitative PCR (qPCR)*

Total RNA was extracted using Tri-reagent (Sigma-Aldrich) from worms exposed to 100 µg/ml 11-nm AuNPs for 24 h in 50% M9 buffer[34] (treated worms) or without NPs (control worms). cDNA was synthesized and quantitative PCR of *elt-2*, *eps-8*, *act-5*, *chc-1* and *dyn-1* was performed using an ABI Prism 7500 FAST platform (Applied BioSystems). All probes were sourced from the Universal ProbeLibrary (Roche) and primers were designed using the Assay Design from Roche (Table S1). We applied the  $\Delta\Delta\text{CT}$  method to calculate the fold change in gene expression for each gene. The gene *rla-1* was used as reference gene. Three biological replicates were analyzed, and four technical repeats were used per sample. Further details of the qPCR methods can be found in the SI file.

### *Statistical analysis*

Past 3.03 was used for all statistical analyses. For the toxicological assays, statistical significance between control and treated worms was assessed using the Student's t-test. Three levels of statistical significance were considered in all cases:  $p < 0.05$  (\*),  $p < 0.01$  (\*\*), and  $p < 0.001$  (\*\*\*)).

## **Results and discussion**

### *Characterization of the material*

The 11-nm citrate-coated AuNPs were synthesized by the Frens Turkevich reaction, as described previously.[30, 31] The 150-nm citrate-coated AuNPs were obtained by seeded growth (Figure S1).[32] Citrate coating is also used in some commercial colloidal gold formulations.[35, 36] The two AuNPs systems were well characterized; obtaining a nominal size for the AuNPs of  $11\pm 1$  and  $150\pm 17$  nm (by TEM); a hydrodynamic mean diameter of  $16\pm 3$  and  $221\pm 49$  nm (by DLS); a zeta potential of  $-26.4$  and  $-21.2$  mV; and a maximum resonance plasmonic absorption band at 525 and 598 nm (by Uv-Vis), respectively (Figure 2).

### *C. elegans exposure to AuNPs*

*C. elegans* were fed with AuNPs in aqueous dispersion for 24 h. During feeding, *C. elegans* pumps liquids by rhythmic contractions of the pharynx and subsequently to the lumen of the intestine.[14] AuNPs were introduced gradually through the alimentary

system and accumulated over a period of 24 hours. Toxicological effects were evaluated by means of survival and brood size assays. We quantified the ingestion of gold by means of inductively coupled plasma mass spectrometry (ICP-MS) and investigated the interaction between the external surface of *C. elegans*, the cuticle, and the AuNPs using scanning electron microscopy (SEM), energy-dispersive X-ray (EDX) spectroscopy, and zeta potential measurements. The pharyngeal cuticle was studied by TEM, and the biodistribution of AuNPs evaluated by light microscopy (LM), TPLM, and TEM, from lower to higher spatial resolution. Remarkably, TEM investigations allowed us to track NP fate at the cellular and subcellular levels, and to evaluate the crossing of biological barriers at single-NP resolution. Finally, the optical status of AuNPs was determined by absorbance microspectroscopy on individual worms utilizing a custom-designed setup as described in the Experimental Section.

### *Toxicity and uptake*

The biocompatibility of the material was evaluated by studying two toxicity endpoints, survival and reproductive performance (brood size) in young adults exposed to 0–500  $\mu\text{g/mL}$  AuNPs. We assessed AuNPs in the concentration range 0–500  $\mu\text{g/mL}$  and observed that 100  $\mu\text{g/mL}$  induced a significant decrease in the survival of 11-nm AuNPs treated worms, compared to control animals (Figure S2), hence we selected this concentration to evaluate the effect of AuNPs in *C. elegans*. A treatment of 100  $\mu\text{g/mL}$  of the small nanoparticles also significantly decreased the reproductive output. Survival and brood size decreases were not statistically significant in the case of the larger NPs (Figure 3A). Previous studies on Ag-NPs also reported toxicity for *C. elegans* survival and reproduction at similar metal doses,[37] while other compositions such as iron oxide were more biocompatible (up to five fold in terms of metal weight).[38, 39] Similarly, other authors reported that smaller NPs ( $\leq 10$  nm) were more toxic to *C. elegans* than larger NPs ( $\geq 50$  nm).[40, 41]

We quantified the uptake of NPs by chemical analysis and found that worms ingested 500 times more 11-nm AuNPs than 150-nm AuNPs. However, the gold mass contained in the worm's body was nearly seven times higher in the case of the large NPs due to the size of the ingested particles. Given that the surface area of ingested NPs was twice as high in worms treated with the 11-nm AuNPs compared to worms exposed to 150-nm AuNPs, and the fact that gold surface atoms are highly reactive, might account for the observed nanotoxicity of the smaller NPs (Figure 3B and Table S2).

Moreover, studies on other inorganic NPs suggested that smaller particles (up to 10 nm) can trigger oxidative stress to a greater extent than larger particles, mainly due to their larger surface area.[40, 41]

In terms of NP uptake per body mass, *C. elegans* ingested  $6\text{--}42 \times 10^5$   $\mu\text{g}/\text{kg}$  AuNPs, which corresponds to a metal dose which is 5–6 orders of magnitude above the maximum prescribed dose for humans. For instance, MesoGold®, marketed in the US as a mineral supplement to enhance the body's immune system, contains a dispersion of 3.2-nm AuNPs at 20  $\mu\text{g}/\text{mL}$  (250 mL), with the recommended adult daily dosage being 4–17  $\mu\text{g}/\text{kg}$ . The worms were treated with metal doses exceeding the human doses, suggesting that the AuNPs are biocompatible. Furthermore, this study emphasises that *C. elegans* can serve as a surrogate animal model, since vertebrates could not be treated under these harsh conditions due to ethical concerns; *C. elegans* can thus fill a gap within toxicological evaluations, despite being a simple organism.

#### *Interaction with the external and pharyngeal cuticle*

The interaction between the external surface area of *C. elegans* and AuNPs was investigated by SEM-EDX (Figure 4). The outer surface of *C. elegans* is covered by an extracellular cuticle, which separates the interior of the body from the environment and acts as an external skeleton.[14] The epidermis of invertebrates is the primitive predecessor of skin in humans and all other vertebrate animals, both structurally and functionally. Therefore, the cuticle and epithelia of *C. elegans* has been used as a simplified skin model for NP assessment *in vivo*. [17, 18] The cuticle comprises five layers, mostly consisting of collagen, lipids, and some glycoproteins (Figure 1A). Structural proteins and lipids are also present in human skin, whereas other components (i.e. keratin or elastin) are specific to mammals.[14] The two protective structures possess a negative surface charge, confirmed by a zeta potential of  $-20.1$  mV for *C. elegans* in MilliQ water. EDX quantitative analysis revealed that AuNPs did not attach to the external surface of the animal (based on the absence of gold). The negative charge of both the cuticle and the citrate-capped AuNPs may explain the lack of affinity between them.[14] Hence, these results imply that NPs do not enter via the dermal route and indicate that the alimentary tract is the main portal of NP entry into the body of the worm in our experiments. The *C. elegans* cuticle also covers the four major openings of the body to the exterior: the anus, the excretory pore, the vulva and the pharynx. However, unlike previous studies using fluorescent  $\text{SiO}_2$ -NPs[42, 43], we did not

observe entrance of NPs through other body openings. The interaction between the pharyngeal cuticle and the AuNPs was investigated by TEM. Adhesion of AuNPs to the pharynx was unlikely, as NPs were distributed inside the pharyngeal lumen and did not attach to the cuticle (Figure 4B,C).

### *Biodistribution*

AuNPs were introduced gradually to the alimentary system and accumulated for up to 24 h in the intestinal lumen. When visualizing AuNPs inside the intestinal lumen of *C. elegans* under transmitted light from a light microscope (LM), the colors of the 11-nm AuNPs appeared pink and the 150-nm AuNPs blue, which is consistent with their absorbance in the UV-Vis (Figure 5B–C and Figure S3). Although the intensity of the color was not uniform throughout the body, no appreciable color change occurred inside *C. elegans*. However, both 11 and 150-nm AuNPs appeared redder in reflected light, likely due to the complex nanoscale color and scattering effects. Absorbance microspectroscopy was employed to obtain a more precise analysis of the optical properties of AuNPs inside the worm.

Exploiting the luminescent properties of AuNPs, we performed TPLM studies to analyze the NP uptake in individual worms at different segments of the intestinal tract, namely the pharynx, the anterior gut, the mid-gut, the posterior gut, and the rectum (Figure 5A). Each segment of the intestinal tract is characterized by a different pH value.[44] Under near-infrared pulsed illumination, AuNPs luminesce via interband transitions induced by the absorption of two photons. This signal is strongly enhanced when the pulsed illumination spectrally overlap with the localized plasmon resonance of the AuNPs.[45-49] TPLM is of particular interest as it can provide an improved AuNPs contrast compared to bright-field or dark-field microscopy, which are often hampered by the endogeneous parasitic scattering of the worms. Furthermore, as multiphoton processes feature a nonlinear dependence on the excitation intensity, TPLM is intrinsically confocal and offers three-dimensional imaging capabilities with improved spatial resolution.

TPLM allows us to visualize AuNPs in a cellular environment,[50] with single-particle sensitivity.[51] This method has been widely used to image functionalized AuNPs targeting cancer cells *in vitro*[49, 52] and AuNPs distribution in mice *in vivo*,[51, 53] but rarely to localize AuNPs inside *C. elegans*. [28] Here, TPLM images

indicated the confinement of AuNPs in the intestine of *C. elegans* and the absence of AuNPs outside the intestinal lumen. By scanning the sectioning plane of the TPLM image, TPLM tomography allowed a three-dimensional reconstruction of the entire worm, confirming the absence of AuNPs adsorbed onto the cuticle and excluding a topical entrance of AuNPs (Figure 5D,E, and Videos S1, S2, S3). Therefore, the toxicological effects of AuNPs can only be attributed to the AuNPs present in the digestive tract of *C. elegans*, and their status (aggregation, surface area, etc.) may play a determining role.

#### *NP localization at the cellular scale*

Ultrathin cross-sections of treated worms were examined by TEM to study the subcellular localization and size of AuNPs inside *C. elegans* and in doing so to determine whether AuNPs are capable of crossing the intestinal barrier. In all cases, AuNPs preserved their monodispersity, were restricted to the intestinal lumen and not internalized by the intestinal cells (Figure 6B-E). We did not visualize NP-containing endosomes, and they remained separate from the microvilli by a peritrophic-like membrane, the glycocalyx, which protects the intestinal cells against foreign materials, mechanical injury, and pathogens. This extracellular electron-lucent coating consists of highly modified glycoproteins, which localizes digestive enzymes and filters the molecules that reach the absorptive surface of the microvilli.[23, 54] Borgonie et al. investigated the passage of different molecules through this protective layer and observed only sparse crossing of ferritin molecules, while it allowed passage of fluorescein isothiocyanate, methyl red, neutral red, and acridine orange.[22] High-angle annular dark-field scanning transmission electron microscopy (HAADF STEM) of animal cross-sections confirmed the absence of NP endocytosis and translocation, as AuNPs were only visualized in the lumen (Figure S4).

Endocytosis or translocation to secondary organs in *C. elegans* have been reported for oxide nanoparticles such as citrate-capped 6-nm Fe<sub>2</sub>O<sub>3</sub>-NPs[39, 55] 50-nm SiO<sub>2</sub>-NPs,[43] and carbon nanomaterials including graphene oxide,[56] bioconjugated nanodiamonds,[57] or carbon nanotubes.[58] Also, endocytic trafficking of metal NPs such as citrate-capped 7-nm Ag-NPs[59] or 4-nm AuNPs[60] has been documented. We tracked AuNPs of two different sizes by a range of techniques and in all cases concluded that no endocytosis occurred within the 24 h incubation period. The absence

of internalization of NPs by the intestinal cells of *C. elegans* could be attributed to the lower transcytotic capacity of the *C. elegans* intestine compared to that of vertebrates. Recent studies in mammals have revealed that the Microfold cells (or M cells) present in the intestinal barrier, which lack the glycocalyx covering and have a poorly organized brush border, are necessary for the absorption of NPs that are administered orally (Figure S5).[61] While little translocation occurs through the enterocytes, especially for negatively charged particles, the coexistence of enterocytes and M cells can increase NP absorption by up to 50-fold.[8, 62] The absence of M cells in *C. elegans* could explain the deficiency of AuNPs translocation. To support the lack of endocytosis of AuNPs, we assessed molecular markers of endocytosis (*chc-1*, *dyn-1*, *eps-8*) and intestinal barrier integrity (*eps-8*, *act-5*, *elt-2*) by qPCR (Figure 7), genes previously reported to be affected by 4-nm AuNPs treatment in *C. elegans*. [60] To validate the qPCR integrity of total RNA/cDNA, positive controls included two metal-responsive transcripts (*mtl-1*, *fm-1*). We found no significant alteration in the gene expression patterns of the above mentioned endocytosis and intestine markers between control and treated worms, except for *act-5* (actin). The expression of *act-5* is limited to intestinal tissue and is essential for microvilli formation. It is conceivable that the down-regulation of *act-5* may be induced by the presence of AuNPs in the intestine, in proximity to the microvilli. In contrast, the expression of *elt-2*, the dominant transcription factor controlling differentiation and function of the *C. elegans* intestine, was not significantly affected by NP treatment.[63, 64] The lack of endocytosis observed by TEM is supported by the basal expression of *dyn-1* (dynamin), involved in the early stages of endocytosis; *chc-1* (chlatrin), involved in vesicle formation during endocytic transit; and *eps-8*, located at the microvilli tips and associated with endocytosis.

Based on the TEM images, no size decrease of the NP core was observed, which confirms that AuNPs are neither degraded nor digested in the intestinal microenvironment of *C. elegans*, at least within the first 24 h (Figure 6F,G). Other NPs such as iron oxide NPs or quantum dots are metabolized inside the *C. elegans* intestine and suffer size decrease or structural collapse.[39, 65] The unchanged size of the AuNPs also indicates that both sizes of NPs passed through the pharyngeal grinder, suggesting that it is only able to break up biological entities such as bacteria but not inorganic materials, which supports previous results obtained with 3- $\mu$ m latex beads.[66]

The monodispersity of the AuNPs inside *C. elegans* and the absence of necking

between them suggest that the citrate coating was preserved inside *C. elegans*, which hence indicates a strong electrostatic interaction between the metallic core of the NP and the surfactant. *In vitro* evaluation of AuNPs in simulated *C. elegans* intestinal conditions confirmed those results. We mimicked the intestinal *C. elegans* microenvironment by incubating the 11-nm AuNPs for 24 h at pH 4.6 with and without 10% fetal bovine serum (FBS). DLS measurements demonstrated that 11-nm AuNPs aggregated under the simulated conditions ranging from an initial hydrodynamic mean size of  $10\pm 2$  nm in MilliQ water to  $900\pm 300$  nm in citrate buffer at pH 4.6. In contrast, 11-nm AuNPs aggregation was reduced ( $180\pm 60$  nm) when FBS was incorporated into the system. UV-Vis spectroscopy revealed a 59-nm red-shift of the maximum absorbance peak when AuNPs were incubated without protein and a mere 6-nm peak shift when FBS was added. TEM analysis further confirmed the degree of aggregation (Figure S6). This *in vitro* study supported our hypothesis that the pH of the specific region of the intestine and the biomolecules present (i.e., proteins) enhance the stability of the AuNPs and prevent the formation of large aggregates, as observed *in vivo*, in the *C. elegans* intestine.

#### *NP status inside C. elegans*

AuNPs have a strong tendency to form large aggregates, especially when they are exposed to highly ionic media. We wanted to evaluate the behaviour of citrate-capped AuNPs *in vivo* in a multicellular biological environment (taking into account ionic strength, pH, space constriction, etc.) and to determine the resulting effects on the material. NP aggregation inside *C. elegans* was monitored by absorbance microspectroscopy measurements along the body of treated worms, in particular at the grinder, the anterior, central and posterior parts of the gut, and the rectum. Aggregation induces a coupling of the AuNPs' plasmon resonance modes, which results in a red shift and broadening of the plasmon resonance.[67] By using a home-made setup consisting of a UV-Vis spectrometer coupled to an optical microscope, we were able to acquire spectra of the AuNPs in the targeted areas of individual *C. elegans* with 10- $\mu$ m precision. At least ten worms per condition were analyzed and the mean spectrum for each part of the worm was plotted (Figure 8A).

Plasmon resonance peak shifts were used to evaluate the aggregation level of the AuNPs when confined in the different anatomical regions. Interparticle distance

changed according to the physioanatomical properties and pH of the different areas of the intestinal tract, inducing specific degrees of aggregation in each region (Figure 8B and Table S3). In all cases we observed a broadening of the absorption band and a red-shift of the peak maxima. No AuNPs were detected by spectroscopy in the reproductive organs.

In the grinder, the 150-nm AuNPs displayed the highest peak shift, due to the space constriction of the pharyngeal lumen. The grinder is made up of three pairs of muscle cells that rotate when the muscles contract and act as "teeth" that break up food.[14] When closed, the pharyngeal lumen is constrained to a diameter of only a few hundred nanometers. In the grinder, the 11-nm AuNPs mediated peak shift was three times smaller than the 150-nm AuNPs. In the anterior intestine, the peak shift was small with both AuNPs, which confirms that AuNPs can redisperse when the width of the intestinal lumen increases, returning to a lower degree of confinement. In this region, the presence of other biomolecules can result in the formation of a protein corona that may enhance the stability of the NPs,[68-70] a notion which warrants further investigations but is not within the scope of this work. Remarkably, the aggregation of AuNPs is not irreversible, but associated with their temporary environment.

After 24 h of feeding, a significant amount of AuNPs accumulated in the posterior region of the gut, promoting low interparticle distance as the space narrowed, which resulted in a red-shift corresponding to ca. 5% of the initial peak position with both AuNPs. LM and TPLM studies showed that both NPs exhibited similar behavior in this region, which we believe is due to the mechanical pumping mechanism that governs the intestinal transit in *C. elegans* rather than being attributable to the AuNPs' properties.

The effect of the pH on NP status should also be considered (Figure 5A). While the pH in the most anterior region of the gut is close to 6, it decreases to ca. 3.5 in the posterior part. [44] *In vitro* experiments showed that the combination of acidic pH and ionic strength of the citrate buffer pH 4.6 promoted the aggregation and precipitation of the AuNPs (Figure S5). Therefore, these conditions may compromise AuNP stability in the most posterior part of the alimentary system.

In the rectal region, the presence of both AuNPs was sparse, which was likely due to the absence of food and thus reduced intestinal activity. However, when worms were transferred to a bacterial lawn and feeding commenced, the intestinal NPs were rapidly excreted in the form of micrometric ejections which were identical in colour as the AuNPs observed inside the worm. The appearance of such ejections suggests that NPs

were mixed with the intestinal content of the worm, typically food debris and endogenous secretions (Figure 9), and suggests that the size of the AuNPs did not change. After 2 h of food consumption, AuNPs were no longer observed inside treated *C. elegans*.

## Conclusions

By employing a combination of microscopy techniques (light microscopy, two-photon luminescence microscopy, and electron microscopy), chemical analysis, absorbance micro-spectroscopy and key life cycle endpoints, we were able to screen the biodistribution of 11-nm and 150-nm citrate-capped AuNPs in the model organism *Caenorhabditis elegans* at several levels, from the whole organism down to subcellular resolution. We confirm that the nanoparticles did not cross the intestinal and dermal barriers, based on the absence of endocytosis and adsorption, respectively, contradicting previous reports suggesting that similar-sized metal nanoparticles are endocytosed.[59, 60] Moreover, our findings indicate that, *in vivo*, the AuNP status is influenced by the physiological properties and the anatomical structure of this model organism, in particular modulating their degree of aggregation and changing their optical properties inside the intestinal lumen where both acidic pH and the presence of biomolecules play an essential role. The transcription of selected markers of endocytosis and intestinal barrier integrity (*elt-2*, *eps-8*, *act-5*, *chc- 1* and *dyn-1*) were not altered in worms exposed to AuNPs.

This study highlights how *C. elegans* can advance our understanding of meaningful nano/bio interactions at different biological levels, ranging from the whole animal down to cells and molecules. Here, we discern the effects of different AuNP sizes with potential applications as biocompatible nanomedicine products and safe cosmetics. This information is of particular relevance for the cosmetic, food, and pharmaceutical industries, as strict regulatory guidelines and high cost restrict the use of animals, especially during drug discovery and initial screening stages.

## Acknowledgements
