Abstract: Composite materials are very promising biomaterials for hard tissue augmentation. The approach assayed in this work involves the manufacturing of a composite made of a bioactive ceramic, natural wollastonite (W) and a nanostructured copolymer of ethylmethacrylate (EMA) and vinylpyrrolidone (VP) to yield a bioresorbable and biocompatible VP-EMA copolymer. A bulk polymerization was induced thermally at 50°C, using 1 wt % azobis(isobutyronitrile) (AIBN) as free-radical initiator. Structural characterization, compressive strength, flexural strength (FS), degradation, bioactivity, and biocompatibility were evaluated in specimens with a 60/40 VP/EMA ratio and ceramic content in the range 0–60%. A good integration between phases was achieved. Greater compression and FS, in comparison with the pure copolymer specimens was obtained only when the ceramic load got up to 60% of the total weight. The soaking in NaCl solution resulted in the initial swelling of the specimens tested. The maximum swelling was

reached after 2–3 h of immersion and it was significantly greater for lower ceramic loads. This result makes the polymer component the main responsible for the interactions with the media. After soaking in SBF, microdomains segregation can be observed in the polymer component that can be related with a dramatic difference in the reactivity of both monomers in free radical polymerization, whereas the formation of an apatite-like layer on the W surfaces can be observed. Biocompatibility *in vitro* studies showed the absence of cytotoxicity of all formulations. The cells were able to adhere on the polystyrene negative control and on specimens containing 60 wt % wollastonite forming a monolayer and showing a normal morphology. However, a low cellular growth was observed. © 2008 Wiley Periodicals, Inc. *J Biomed Mater Res* 88A: 53–64, 2009

INTRODUCTION

The design of biomaterials and scaffolds for hard tissue engineering must allow ease of handling in

the preparation and implementation of implant materials; furthermore, the implants must have the capacity to be trimmed or sculpted to exactly, fit every surgical site and exhibit a rapid and reproducible degradation or dissolution process in every insertion site.¹

Mechanical stability and capacity for being osseointegrated are the key features for the success of a bone substitute. Osseointegration requires matching the degradation rate of the substitute to the growing rate of the tissue.

Several approaches have been used to reach this goal, mostly involving the introduction of a bioactive ceramic such as hydroxyapatite² or bioglass.³ Several phase composites containing a resorbable polymer and a reinforcing ceramic⁴ is between the most

promising methods proposed though no ideal bone prostheses have been produced yet.⁵

The approach suggested in this work involves the manufacturing of a composite made of a bioactive ceramic, natural wollastonite, and a nanostructured copolymer with a biostable component, ethylmethacrylate (EMA) and a bioresorbable component, vinylpyrrolidone (VP). These sort of multiphase materials have also shown the ability to create porosity *in situ* when they are in contact with physiological fluids.⁶

There are two polymorphs of wollastonite; the high temperature form known as pseudowollastonite (β -CaSiO₃, ps-W), and wollastonite-Tc (α -CaSiO₃, W-Tc), the form stable at temperatures below 1125°C.⁷ Ps-W ceramics react in simulated body fluid (SBF) forming an apatite layer on their surface.⁸ They are not cytotoxic^{9,10} and induce calcification in osteoblast cultures *in vitro*.^{11,12} New woven bone is directly deposited on ps-W implants during *in vivo* test in rat tibiae also.^{13,14} Ps-W ceramics obtained by solid-state reaction of synthetic precursors presented similar chemical, mechanical, and biological properties than ps-W ceramics obtained by sintering powders of natural W-Tc.¹⁰ W-Tc ceramics are not available because of the low transition temperature to ps-W and the relatively high temperature required for sintering and densification of the precursor powders into a ceramic body. However, synthetic powders of W-Tc exhibit *in vitro* bioactivity also.¹⁵ Wollastonite powders and sponges have been employed as fillers in several experimental biomedical composites. Porous ceramic sponges of synthetic ps-W impregnated with a mixture of EMA and VP monomers rendered by thermal polymerization reinforced and *in vitro* bioactive composites.^{16,17} Biomedical composites of powdered synthetic and natural W-Tc with polymeric matrixes of poly(3-hydroxybutyrate-co-3-hydroxyvalerate)^{18–20} poly(D,L-lactic acid),²¹ poly(butylene terephthalate),²² collagen²³ and chitosan,²⁴ have been reported, which exhibit better mechanical strength and bioactivity with regards to the polymer component alone.

Block copolymers of segments with different solubility properties have been of considerable interest in different fields such as sequestration of pollutants, drug delivery, or gene therapy due to their ability to self-assemble in bulk state.²⁵ VP copolymers have been tested as a vehicle for controlled local application of growth factors. VP acts as a biodegradable support containing the substance to be delivered and the release rate is controlled by the resorption profile of the copolymer composition.^{26,27} VP has also been tested for the release of the nonsteroidal anti-inflammatory drug 2'4'-difluoro-4-hydroxy-(1,1'biphenyl)-3-carboxylic acid²⁸ and the immunosuppressor cyclosporine A.²⁹ The proteic³⁰ and blood³¹ interactions of copolymers of VP have also been studied.

Methacrylates have been used in the preparation of acrylic cements^{32,33} used in surgery to fix joint replacements. PEMA bone cements have been investigated as an alternative to PMMA due to their higher ductility, lower toxicity, and exotherm,³⁴ water absorption-desorption characteristics, and interactions with the biological medium studied.³⁵ PEMA derivatives have been studied for the preparation of intervertebral cages³⁶ and as carriers for the recombinant human bone morphogenetic protein 2³⁷ and fosfosal.³⁸

The production of composites based on the *in situ* polymerization of EMA and VP with several amounts of dispersed W-Tc is presented in this article. The maximum ceramic load that can be achieved is investigated and the influence of the ceramic load on the resorption rate of the specimens and on the features of the apatite layer growth when the specimens are soaked in an acellular SBF is assessed. The influence of the inorganic load in the biocompatibility of the system is also assessed.

The optimization of the resorption rate and the control of the bioactivity in the design of hybrid inorganic-organic composites is the goal pursued.

EXPERIMENTAL SECTION

Specimen preparation and characterization

A natural wollastonite (W-Tc) (Vansil[®] W40, Vanderbilt), with an average particle size of 13.2 μ m and 1.056 $\pm$ 0.001 SiO₂/CaO molar ratio, was selected as the ceramic component. Qualitative X-ray diffraction analysis showed that the major crystalline phase was α -CaSiO₃, also called CaSiO₃-Tc (JCPDF 43-1460). Minor amounts of prehnite (2CaO·Al₂O₃·3SiO₂·H₂O, JCPDF 29-0290), and diopside (Ca (Mg,Al)₂(Si,Al)₂O₆, JCPDF 41-1370) were also detected.¹⁰ 1-Vinyl-2-pyrrolidone (VP) (Aldrich) and EMA (Acros) were chosen as the organic components for the preparation of the copolymer system.

Prior polymerization, VP, and EMA monomers were distilled at reduced pressure. The monomers were mixed in a VP/EMA 60/40 weight ratio and the ceramic component added in different ceramic/polymer weight ratios: 0/100, 15/85, 30/70, and 60/40. The resulting specimens will be named W0, W15, W30, and W60. A bulk polymerization was induced thermally at 50°C using 1 wt % azobis(isobutyronitrile) (AIBN) as free-radical initiator by introducing the desired composition into a 15 mm diameter cylindrical plastic mold. The molds were filled to a height of 100 mm. Discs of 1 mm height were sliced with a diamond saw using alcohol as lubricant after removing the cylinders from the mold and discarding 10 mm length at each end. Plastic molds (6 mm) were also filled and 12 $\times$ 6 cylinders manufactured in the same way. 45 mm length $\times$ 6 mm width $\times$ 4 mm depth teflon molds were also employed.

Specimens with a ceramic/polymer ratio 60/40 and EMA as the solely organic component and films without

the ceramic component were fabricated in an analogous manner for extra testing.

The specimens were characterized by thermogravimetric analysis (TGA), differential scanning calorimetry (DSC), ^1H nuclear magnetic resonance (NMR), attenuated total reflectance Fourier transformed infrared spectroscopy (ATR-FTIR), X-ray diffraction (XRD), scanning electron microscopy (SEM) and atomic force microscopy (AFM).

TGA was performed in a Perkin-Elmer TGA 7, three different slices were analyzed to calculate the average value. 10–20 mg of the composites were heated at a $10^\circ\text{C}/\text{min}$ rate between 50 and 600°C . DSC experiments were performed in a Perkin-Elmer DSC7. The specimens were heated between 35 and 250°C at a rate of 10°C in flowing nitrogen gas. Glass transition temperature (T_g) was estimated from the midpoint of the tangent at the inflection point on the second heating scan. ^1H NMR spectra were recorded in a Bruker Avance-300 working at 300 MHz after extracting the polymeric component in CDCl_3 . ATR-FTIR spectroscopy was performed with a Perkin-Elmer Spectrum one spectrophotometer. Sixteen scans with a 2 cm^{-1} resolution and 45° incident angle were recorded between 600 and 4000 cm^{-1} with a KBr window yielding an analysis depth of 1–2 μm . XRD patterns were recorded in a Siemens D5000 diffractometer in glazing angle mode using $\text{CuK}\alpha$ radiation, 1.5418 Å, at an incident angle of 0.5 between 20 and 35 with a step of 0.02 Å and 10 second per step. Scanning micrographs were taken with an environmental microscope Phillips ESEM XL30 and a Hitachi S4700 field emission microscope field emission microscope. Energy dispersive X-ray analysis (EDAX) and X-ray mapping were applied to identify the elemental distribution. AFM experiments were performed with a Nanoscope IVa controller in a Veeco Multimode. The results were obtained in tapping mode AFM with a phosphorous doped Si cantilever with a oscillation frequency of 217–249 kHz. The average roughness for each sample was calculated directly from the AFM images.

Mechanical properties

Compressive strength (CS) was measured on the $12 \times 6\text{ mm}^2$ cylinders with an Instron universal testing machine 3366 with a 5 kN load cell and a crosshead speed of 0.5 mm min^{-1} . CS was calculated according to the 5833 ISO Standard with the following formulae

$$\text{CS} = \frac{F}{A} \quad (1)$$

where F is the breakload and A the section area of the specimen.

Flexural strength was measured in a three-point configuration in a Microtest EM/50/Fr equipped with a load cell of 0.5 kN. The measurements were done following the ASTM D 790-95a standard. The outer span was 25 mm and the crosshead speed was 1 mm min^{-1} . The flexural strength (FS) and flexural modulus of elasticity (E_f) according to the expressions valid for a three point bending configuration

$$\text{FS} = \frac{3PL}{2bd^2} \quad (2)$$

$$E_f = \frac{L^3m}{4bd^3}$$

where P is the breakload, L is the support span, b is the specimen width, d is the specimen thickness, and m the slope of the tangent to the initial line portion of the load deflection curve. The results are the average of at least five specimens.

Analysis of variance (ANOVA) was performed by using Statistica 6.0 software (Statsoft, Tulsa, USA). The statistical analysis of wollastonite reinforced specimens was made with respect to wollastonite absent composition used as control, $*p < 0.05$.

Degradation and bioactivity

The kinetics of water absorption and solubility was studied by immersing disks ($n = 3$) of 14 mm diameter and 1 mm thickness in 9 g/L NaCl solution (0.1 mL/mm^2) at 36.5°C and monitoring the weight of the damped disks after different intervals of immersion time. The percent of water uptake (W_t) was calculated from the initial dry mass of the disks (m_0) and the mass of the damped disks (m_t) after certain immersion time by Eq. (4).

$$W_t = \frac{(m_t - m_0)}{m_0} \times 100$$

Solubility (S) in percent was calculated from m_0 and the mass of the disks after the longest immersion time, water rinsing and drying to constant weight (m_f), by using Eq. (5).

$$S = \frac{(m_f - m_0)}{m_0} \times 100$$

In vitro bioactivity was tested by immersing disks into Kokubo's corrected SBF³⁹ at 36.5°C for up to 3 weeks. A volume/area ratio of 0.5 mL/mm^2 was used and the SBF was removed and replaced with a fresh portion at alternate days. Soaked specimens were analyzed by NMR, ATR-FTIR, XRD, SEM, and AFM.

Biocompatibility studies

Phosphate buffered solution of pH = 7.4 (Sigma) was used as received. Thermanox[®] (TMX) control discs were supplied by Labclinics S. L. Tissue culture media, additives, trypsin and 3-(4,5-dimethylthiazol-2-yl)-2,5 diphenyl-tetrazolium bromide (MTT), were all supplied by Sigma. The fetal bovine serum was supplied by Gibco and the Alamar Blue reagent by Serotec.

Specimens and cell culture medium

The negative control was tissue culture plastic, TMX, and the positive control (toxic agent) was an aqueous solu-

tion of Triton X-100. Discs of 10 mm diameter and 1 mm thickness of the cured systems and the controls were used for direct and indirect biocompatibility experiments. At the beginning of the experiment all specimens were sterilized with ethylene oxide. Some specimens were alternatively sterilized with β -radiation. A dose of 20 kG was supplied to the specimens using an electron accelerator Rhodotron TT2 working at 50 kW and 10 MeV.

The cells used in the primary cell culture were human fibroblasts cultured at 37°C in humidified air with 5% CO₂. The culture medium was minimal essential medium Eagle (MEM), modified with HEPES [4-(2-hydroxyethyl)-1-piperazine ethane sulfonic acid] (Sigma) and supplemented with 10% fetal bovine serum, 200 mM L-glutamine, 100 units/mL penicillin and 100 μ g/mL streptomycin. The culture medium was changed every 2 days with care to cause little disturbance to culture conditions.

Environmental scanning electron microscopy

The materials were placed in a 24-well plate (in duplicate) and seeded with fibroblasts at a density of 14×10^4 cells/mL. These were incubated at 37°C in humidified air with 5% CO₂. The cells were fixed with 1.5 % glutaraldehyde buffered in 0.1M phosphate buffer after a 24-h incubation period. The dried samples were sputter-coated with gold before examination under an environmental scanning electron microscopy (ESEM) apparatus (Philips XL 30) at an accelerating voltage of 15 KeV.

MTT assay

To evaluate the cytotoxicity of the "leachables" obtained from the cured cements, TMX, Triton and discs of formulations were first set up in 5 mL of MEM and placed on a roller mixer at 37°C. The medium was removed at 1, 2, and 7 days, and replaced with 5 mL of fresh medium. All the extracts were obtained under sterile conditions. Human fibroblasts were seeded at a density of 11×10^4 cells/mL in complete medium in a sterile 96-well culture plate and incubated to confluence. After 24 h of incubation the medium was replaced with the corresponding dilution or eluted extract and incubated at 37°C in humidified air with 5% CO₂ for 24 h. A solution of MTT was prepared in warm phosphate buffered solution (0.5 mg/mL) and the plates were incubated at 37°C for 4 h. Excess medium and MTT were removed and 100 μ L dimethylsulphoxide were added to all wells to dissolve the MTT taken up by the cells. This was mixed for 10 min and the absorbance was measured with a Biotek ELX808IU spectrometer using a test wave length of 570 nm and a reference wave length of 630 nm. The cell viability was calculated from Eq. (6):

$$\text{Relative cell viability (\%)} = 100 \times \frac{\text{OD}_S - \text{OD}_B}{\text{OD}_C}$$

where OD_S, OD_B, and OD_C are the optical density of formazan production for the sample, blank (MEM without cells) and the corresponding control, respectively.

Alamar Blue assay

Human fibroblasts were seeded at a density of 14×10^4 cell/mL over the testing dry specimens placed in 24-well culture plate for 24 h. After that, 1 mL of Alamar Blue dye (10% Alamar Blue solution in phenol red free DMEM medium) was added to each specimen. After 4 h of incubation 100 μ L ($n = 4$) of culture medium for each test sample were transferred to a 96-well plate, and the absorbance was measured at 490 nm on a Biotek ELX808IU spectrometer. The specimens were washed with phosphate buffered solution twice to remove rest of the reagent, and 1 mL of culture medium was added to monitor the cells over the materials. This step was done at 4, 7, 14, and 21 days.

Statistical analysis of biocompatibility test

ANOVA was performed by using Statistica 6.0 software (Statsoft, Tulsa, USA). The statistical analysis of MTT, Alamar Blue was made with respect to TMX control, * $p < 0.05$.

RESULTS AND DISCUSSION

Specimen characterization

The specimens loaded with the ceramic component were characterized first by TGA. A weight loss between 316 and 480°C can be observed for each of the compositions analyzed as displayed in Figure 1 (dashed curves), which corresponded to the decomposition and volatilization of the polymer component on heating. From the weight loss ceramic/polymer ratios of the specimens were calculated. Ceramic/polymer weight ratios obtained for W15, W30, and W60 are: 17/83, 33/67, and 72/28. The deviation

Figure 2. Structure and spectrum of a W0 specimen.

from the ratios utilized for the synthesis was lower than 3% for those specimens with less than 60% of W-Tc theoretical contents suggesting a reliable preparation procedure. However, remarkable deviation was observed for the specimen W60 probably due to sedimentation of the filler during the thermal polymerization in the cylindrical plastic moulds.

All the weight loss occurred in one single step at a relatively high temperature but the relative stabilization of thermal degradation with respect to pure homopolymers have been reported for several systems including methacrylate units^{40,41} whereas the cleavage of the pyrrolidone ring that could be expected between 280 and 300°C has also been observed at greater temperatures as a consequence of the volatilization of the pyrrolidone residue that proceeds from polyenic sequences formed at those temperatures.^{40,41}

The DSC analysis of the copolymer specimens without the ceramic component showed a unique T_g at about 60°C that is very close to the theoretical value for PEMA.⁴² When the ceramic component is added the T_g value shifts to 88°C, suggesting that an interaction between the ceramic and the polymeric components does happen. No significant differences could be appreciated between specimens with different ceramic load.

Polymerization was confirmed by ^1H NMR spectroscopy. Figure 2 displays the spectrum of the copolymer for a W0 specimen. The spectrum corresponds to a random EMA/VP copolymer with an average weight composition 60/40 which was determined from the comparison of the resonance signals of the oxyethylene groups of EMA units (4.1 ppm) and those assigned to the pyrrolidone ring (3.4 ppm). Results for each of the compositions are shown in Table I.

The SEM images and Ca and Si mappings displayed in Figure 3 show that the specimens are made of acicular W-Tc particles distributed within a homogeneous polymeric matrix. No cracks between the organic and the inorganic phase can be observed indicating that a good integration between phases was achieved.

Mechanical properties

The CS results of the composite specimens are shown in Table I. Compression strength is greater for W60 than for the copolymer specimens W0. W30 and W15 compression strength results are not significantly different from W0. The elasticity modulus in compression mode is also displayed in Table I. A 47% and 20 % increase for the W60 and W30 specimens in comparison to the non-reinforced specimens (W0) was obtained whereas the W15 composition does not show a significant increase in elastic modulus compared with the non-reinforced specimen.

Flexural strength results are also collected in Table I. Each of the ceramic reinforced compositions shows a greater FS than the non-reinforced copolymer specimens. Again, the maximum FS was achieved for the composition with a 60% of ceramic load. W15 and W30 compositions showed no significant difference between them, but their values are significantly lower than those of W60. The elasticity modulus calculations in bending yield greater values for greater ceramic loadings.

Bending fracture surfaces are displayed in Figure 4 revealing the influence of filler particles on the deformation of the copolymer. W0 fracture surface is

Figure 5. Kinetics of water uptake for the noncharged copolymer and the experimental composites. —○—: W0; -◇-: W15;: W30; —△—: W60.

shown in Figure 4(a) and a magnification is displayed in Figure 4(e). The polymer is highly deformed with elongated domains that indicate a ductile fracture. W15 fracture surfaces show ceramic particles and agglomerates with copolymers domains surrounding them with no apparent voids between phases, domains are less deformed indicating a lower ductile character of the fracture, Figure 4(b,f). Broken ceramic particles and less deformed polymer matrix were observed for greater ceramics loads indicating fragile fractures, Figure 4(c-d,g-h).

Some studies in particulate filled resins have shown that a low degree of adhesion between the particles and the matrix produces a decrease in yield stress.⁴³ Other studies in particulate filled PMMA cements have shown that the poor adhesion between the filler and the matrix can be compensated by increasing the filler content resulting in constant values of the yield stress.⁴⁴ The studied compositions seem to reproduce

this compensation mechanism where only the effects of the greater amount of filler content totally overcome the effect of the lack of adhesion resulting in a greater compression strength. However, in bending mode, the ceramic particles seems to interact with the polymer repressing the ductile behavior of the polymer as it can be observed in the fracture surface and increasing the value of the fracture stress. Maximum bending stress was reached at values over 50% of filler content in good agreement with results obtained in polyethylene composites.⁴⁵ There are several mechanisms that can explain the improvement in the fracture stress in bending of particulate reinforced polymers, one of them is known as crack pinning.⁴⁶ If a crack begins to propagate within a material, the crack front bows outward between two rigid particles before breaking free. The crack front elongates as it bows out, absorbing fracture energy. Separation of the filler from the matrix also absorbs energy. As the advancing crack intersects with particles a further opening of the tip requires extra energy to separate the filler matrix interfaces. Poorly bonded fillers do not contribute effectively to toughening through this mechanism. Thus, the improvement in the bending stress of the reinforced specimens together with the shift from ductile to fragile behavior observed in the scanning micrographs seems to indicate some sort of interaction in the selected system.

Elastic modules in compression were all greater than the elastic modulus of PMMA cements determined to be 1.6 GPa⁴⁷ and closer to the compressive modulus of compact bone for femur reported to be up to 17 GPa⁴⁸ and they are greater than the values obtained for several calcium phosphate cements, reported to range between 0 and 51 MPa.⁴⁹ Thus, these compositions have the mechanical behavior appropriate to consider them as good candidates for bone or dental replacement. However, wollastonite

seems to be little studied as filler material in dental replacements.⁵⁰

Degradative behavior/bioactivity

The soaking in NaCl solution resulted in the initial swelling of the specimens tested. The maximum swelling was reached after 2–3 h of immersion and it was significantly greater for W0 and W15 than for W30. The maximum swelling of W30 was also greater than that of W60. These results make the polymer component the main responsible for the interactions with the media, which are the driving forces of the water uptake. At the macroscopic scale, the porosity of the polymer matrix should be the main factor for water absorption through capillarity phenomena, whereas in microscopic terms, the highly hydrophilic VP rich moieties existing in the

copolymer chains must provide them with water-binding capacity through hydrogen and dipole–dipole Van der Waals bonding. The matrix–filler interface seems to have none effect on the water absorption of the composites.

The kinetic curves of Figure 5 also revealed that, after reaching the corresponding values of maximum swelling, the copolymer and the experimental composites started to lose weight due to dissolution. The values of *S* found were 35.9 ± 1.6 , 33.2 ± 1.8 , 24.9 ± 1.5 , and $13.9 \pm 2.0\%$ for W0, W15, W30, and W60, respectively, and diminished as the W-Tc content increased suggesting that the EMA/VP copolymer is more soluble than the W-Tc filler. After finishing the soaking in NaCl solution the specimens were submitted to NMR and TGA to determine possible changes in copolymer composition and ceramic/polymer weight ratio due to incongruent dissolution of the composite.

Figure 8. FTIR spectra of (a) VP/EMA 60/40; (b) VP/EMA 60/40 soaked CaCl_2 48 h (c) EMA 100%; (d) EMA 100% soaked CaCl_2 48 h.

The results are shown in Table I. The ceramic/polymer weight ratio grew after the immersion in NaCl as expected, due to the partial dissolution of the copolymer component of the composites whereas the sparingly soluble W-Tc was not affected. However, the VP/EMA ratio in soaked samples remained almost invariable ($\cong 1.5 \pm 0.1$) suggesting either congruent dissolution of the copolymer or more likely as it will be discussed later a dissolution of the VP domains that remain absorbed on the surface of the W component.⁵¹ This result indicates a homogeneous microstructure of the copolymer characterized by uniform distribution of both monomers in the copolymer chains.

In contrast to as prepared composites, after soaking in saline for 22 days the TGA curves of the specimens W15, W30, and W60 presented multistep weight reductions (Fig. 1, solid curves). The first step in weight loss between 60 and 160°C, ranging between 1 and 3% and directly related to the polymer content, could be assigned to the removal of absorbed water. The second event started at 280°C and extended to 375–400°C. The weight loss related to this event were 38, 28, and 15% for W15, W30,

and W60, respectively, and is probably caused by the releasing of pyrrolidone side groups^{40,41} and the depolymerization of the saturated products of the disproportion of poly(ethyl methacrylate) sequences in the copolymer chains.^{52,53} From 375–390°C to 460°C a third step could be distinguished due to the decomposition of the polyenic sequences remaining from the poly(vinylpyrrolidone) moieties, into low-molecular weight hydrocarbon compounds,^{40,41} as well as the continuing depolymerization of the products of disproportion of poly(ethyl methacrylate).^{52,53} The corresponding weight loss were 31, 23, and 12% for W15, W30, and W60, respectively. The better resolution of the thermal effects in soaked specimens can be explained by the increase of porosity originated by partial dissolution of the polymeric matrix, which contributes to the faster removal of the volatile decomposition products from the composites bulk.

After soaking the specimens in SBF for a week, two different phenomena were observed (a) in the polymeric matrix, a porous nanostructure was formed [Fig. 6(a,b)] indicating microdomains of different solubility. Those zones that appeared to be dissolved should be related to the more resorbable VP rich microdomains, whereas those zones that seems to be unaffected by the immersion should correspond to the more stable EMA rich domains. This microdomain segregation can be related with a dramatic difference in the reactivity of both monomers in free radical polymerization; (b) on the W surfaces, the formation of an apatite-like layer was observed by SEM [Fig. 6(c)], which after studied by ATR-FTIR and low angle XRD could be attributed to a carbohydroxyapatite (CHA). The thickness of the layer is greater for greater percentages of W. At 60 wt % of W all the composite was covered with a thick layer of CHA.

The growing rate and thickness of the apatite layer seems to be lower than the layer observed in other systems.⁵⁴ An inhibition of the growing of the apatite layer is thought to be related to an interaction between the VP component and the Ca of the SBF. Films containing a 60/40% VP/EMA and 100% EMA were prepared in an analogous way than the former specimens and soaked in CaCl_2 solution to test this hypothesis. AFM analysis on the surfaces of the films permitted to appreciate the different behavior of the films whether VP was present or not. Figure 7(a,b) shows the surface of the VP/EMA 60/40 and EMA100 films. The presence of VP leads the mean roughness measured from the 1 μm scan of the films from R_a 0.294 nm for EMA100 to R_a 0.665 nm for VP/EMA60/40. After soaking, EMA 100 film surface seems similar than before but with a roughness of R_a 0.665 nm. The surface of the VP/EMA film was not homogeneous anymore showing the appearance of some structures that lead the rough-

Figure 9. SEM images ($\times 500$) of human fibroblasts colonization over the control (TMX) (a), the W60 material sterilized with ethylene oxide (b) and with β -radiation (c) at 1 day.

ness to Ra 4.911 nm suggesting a stronger interaction with the solution either with the water due to the hydroscopic nature of the VP or with the calcium. The IR spectrum of the 60/40 film soaked for 48 h [Fig. 8(b)] showed the disappearance of the band at 1629 cm^{-1} assigned to the carbonyl group from the VP component whereas no significant differences may be observed in the spectrum of the soaked 100% EMA film, [Fig. 8(d)]. These results suggest the interaction of the calcium with the VP component in a way that can interfere with the initial stages of formation of the layer of carbonateapatite in bioactive materials.

Biocompatibility studies

Results of direct contact of cells with materials after 1 day of seeding are shown in Figure 9. In all micrographs flattened fibroblasts were observed over the surfaces. Fibroblasts showed no evidences of morphological changes after 24 h of incubation in the presence of W60 material when compared with control independently of its form of sterilization: ethylene oxide or β radiation.

MTT assay was used to measure cell metabolic function. This test is dependent on the intact activity

of a mitochondrial enzyme, succinate dehydrogenase, which may be impaired after exposure of cells to toxic species.⁵⁵ MTT results showed the absence of mitochondrial damage in any of the experimental formulations. All the compositions present a biocompatibility at least of the level or even superior than the TMX control as can be seen in Figure 10.

Cell growth and proliferation were assessed by Alamar Blue assay. AB is a redox indicator that changes color with the chemical reduction of the culture medium occurring as the result of cells growth and proliferation. This reagent can be withdrawn and replaced with fresh medium, for monitoring cell proliferation. It is soluble, stable in culture media and nontoxic to cells.⁵⁶

Results from this assay are shown in Figure 11. The number of cells adhered to materials were less than to the control, but when increasing the amount of W in each formulation, cells growth and proliferate better, although without reaching the values for the control. This behavior can be explained based on the high roughness of the materials. It is known that the cell behavior depends on surface roughness and surface free energy.⁵⁷

In vitro biocompatibility studies showed the absence of cytotoxicity of all formulations. The cells

Figure 10. MTT cytotoxicity results for the control and the “leachables” of test materials. Results are the mean $\pm$ standard deviation; $n = 8$; (* $p < 0.05$ respect to control).

Figure 11. Direct Alamar Blue results for control TMX and formulations over a 21-day period. Results are the mean $\pm$ standard deviation; $n = 8$; (* $p < 0.05$ respect to control).

were able to adhere on the TMX control and W60 formulation forming a monolayer and showing a normal morphology. However, there was less cellular growth with respect to control (TMX) as it can be observed in the Alamar Blue assay. This phenomenon may be due to the surface properties. Surface roughness of our specimens is very high and it is difficult for cells to adhere and growth. Glass ceramic formulations with polished and smooth surfaces improve the cell adhesion and cell proliferation.⁵⁸

CONCLUSIONS

The results suggest that wollastonite-poly(VP-co-EMA) composites provide with new bioactive materials that are able to develop nanoporous structures in physiological conditions. Mechanical properties of the system make it suitable for bone substitution. The highest ceramic load is the most promising composition due to the combination of good mechanical behavior, bioactivity, and biocompatibility with appropriate surfaces for cell proliferation.
