## Abstract

Mesoporous Ni and Cu-Ni (Cu<sub>20</sub>Ni<sub>80</sub> and Cu<sub>45</sub>Ni<sub>55</sub> in at.%) films, showing a three-dimensional (3D) porous structure and tunable magnetic properties, are prepared by electrodeposition from aqueous surfactant solutions using micelles of P123 tri-block copolymer as structure-directing entities. Pores between 5 nm and 20 nm and dissimilar space arrangements (continuous network versus open-cell morphologies) are obtained depending on the synthetic conditions. X-ray diffraction reveals that the Cu-Ni films have crystallized in the face-centered cubic structure, are textured, and exhibit certain degree of phase separation, particularly those containing a higher Cu content. Atomic layer deposition (ALD) is used to conformally coat the mesopores of one of the Cu-Ni films (Cu<sub>20</sub>Ni<sub>80</sub> in at.%) with amorphous Al<sub>2</sub>O<sub>3</sub>, rendering multiphase “nano-in-meso” metal-ceramic composites without compromising the ferromagnetic response of the metallic matrix. From a technological viewpoint, these 3D nanoengineered composite

films could be appealing for applications like magnetically-actuated micro/nano-electromechanical systems (MEMS/NEMS), voltage-driven magneto-electric devices, capacitors or as coatings with superior strength and tribological performance.

## **1. Introduction**

Mesoporous metallic materials with high electroconductivity and surface area have sparked much attention during recent years owing to their wide range of applications in areas such as electronic devices, catalysis, energy technologies or even recording media [1]. Their intrinsically porous structure has proven to be useful for the adsorption, selection, sensing, removal, storage and release of second-phase materials [2-7]. Given their large potential, several techniques have been developed during the last decades in order to generate controlled nanoporosity, either by selective etching from the fully dense counterparts (e.g., dealloying or foaming) [8-9] or spontaneous association of small building blocks while leaving empty spaces in between (bottom-up approach) [10-12]. From the viewpoint of material's architecture, control of the alloy composition needs to be often combined with precise tailoring of the mesoporous morphology, pore alignment, and orientation. This still remains a challenging issue. Most approaches rely on relatively slow, multi-step, synthetic procedures, sometimes including costly clean room facilities. Ideally, such materials should be synthesized in a series of easy steps (preferably in a single- or two-step) allowing for a simple but precise control of the shape and morphology of the obtained structures.

During the last few years, mesoporous metals and alloys have been extensively prepared by means of sacrificial templates, using the replication method, from either soft or hard templates [13,14,15]. In the case of the templated deposition of metals, their growth from the substrate is guided by the template and the mesoporous structure often

emerges once after the template is removed. Very recently, the usage of spherical micelles of di-or tri-block copolymers (e.g., polystyrene-*block*-poly(oxyethylene) (PS-*b*-PEO known as KLE or Poly(ethylene glycol)-*block*-poly(propylene glycol)-*block*-poly(ethylene glycol) known as P-123) in water as soft-templates has been demonstrated for a number of metals (e.g., Au, Pt, Pd, Cu) [16-19] and alloys like Pt-Cu, Pt-Ru, Pt-Fe and Cu-Ni [20-24]. Different from the evaporation-induced self-assembly approach, metal deposition and micelles assembly take place simultaneously in liquid phase without involving any solvent evaporation. Furthermore, because the concentration of the block copolymers is above the critical micelle concentration (cmc) but well below the threshold for the formation of liquid crystal structures [25], the viscosity of the electrolyte is kept to the minimum.

The advances in the synthetic pathways to produce magnetic materials with different nanoarchitectures has boosted the discovery of new magnetic phenomena and, in turn, expanded the range of applications of magnetic materials, since many magnetic properties of materials rely on surface or interface phenomena [26]. In this context, very recently, we demonstrated that magnetic mesoporous metallic materials, with an increased surface area-to-volume (S/V) ratio, show enhanced magneto-electric phenomena compared to fully-dense films with analogous compositions [24]. The system under study was Cu-Ni and mesoporous films of this alloy were successfully prepared by electrodeposition from ‘micelles assembly’ of P-123 in water. The coercivity of the as-prepared mesoporous Cu-Ni films could be drastically decreased by simply applying an external electric field. In our previous work, however, only the general features concerning the mesoporous organization of the films were introduced. Instead, emphasis was laid on the electrically-driven modification of magnetic

properties whereas the key experimental factors enabling the formation of the mesoporous structure were mostly overlooked.

Remarkably, besides the aforementioned magneto-electric effects, magnetic mesoporous metallic materials can also be successfully employed as supports to host other functional materials that could bring biocompatible, hydrophilic/hydrophobic properties, electrical insulation or even enhanced mechanical or magnetic performance [27]. For example, 3D macroporous Ni films prepared by the hydrogen bubble templating approach can function as scaffolds to anchor electrodeposited  $\text{Co(OH)}_2$  nanoflakes or sputtered Si to produce nanoporous composites with superior supercapacitor and electrochemical performance [28,29]. In the case of mesoporous materials of metallic nature, an appropriate technique should be carefully selected in order to conformally coat the mesopores with a second-phase material while avoiding or minimizing its oxidation and eventual pore collapse. Atomic layer deposition (ALD) turns out to be a powerful deposition technique that allows not only precise control over the composition of the deposited materials, but also these can continuously coat high aspect-ratio substrates (REFS). In fact, we proposed the combination of electrodeposition and ALD to prepare composite layers consisting of 3D macroporous magnetic metals coated with metal oxide nanolayers, *i.e.*, Ni/ $\text{Al}_2\text{O}_3$ , Ni/ $\text{Co}_2\text{FeO}_4$  [30]. It was demonstrated that both the porosity and the magnetic properties of the electrodeposited metallic matrix were maintained after the ALD step after careful selection of the ALD parameters. However, the ALD deposition was only tested on metallic films exhibiting large pore sizes, of the order of 5-15  $\mu\text{m}$ . It is envisaged that such synthetic approach might not be restricted to macroporous substrates and could be thus well applied to out-of-sight surfaces of nanometric sizes (e.g., mesopores) grown by surfactant-assisted electrodeposition.

In this work, Cu<sub>20</sub>Ni<sub>80</sub>, Cu<sub>45</sub>Ni<sub>55</sub> and Ni magnetic mesoporous films are electrodeposited in the presence of P-123 tri-block copolymer dissolved in the aqueous electrolyte. The growth of mesoporous Ni coatings was carried out under potentiostatic mode, whereas Cu-Ni alloys were fabricated under galvanostatic means. Although all samples show mesoporosity, depending on the synthetic conditions, the resulting morphologies (e.g., pore alignment) are different. Insulating Al<sub>2</sub>O<sub>3</sub>, with a high dielectric constant is chosen to coat the Cu<sub>20</sub>Ni<sub>80</sub> frameworks (which is taken as a model) by means of ALD. The structure and magnetic properties of the films, before and after the ALD process, are studied in detail.

## 2. Experimental Section

All the chemicals were purchased from Sigma-Aldrich and used without further purification. Electrochemical fabrication of nanoporous Ni and Cu-Ni films was carried out in a PGSTAT120N Autolab potentiationstat/galvanostat (electrochemie) with a standard three-electrode cell system. Si/Ti (25 nm)/Au (125 nm) substrates (working area 0.25 cm<sup>2</sup>) were used as cathode. A platinum wire served as counter electrode. The cathode and anode were mounted parallel to each other at a distance of 2 cm. A double junction Ag | AgCl 3 M KCl electrode ( $E = + 0.210$  V *versus* standard hydrogen electrode (SHE)) was utilized as the reference electrode. The optimized growth parameters for the electrodeposition of nanoporous Ni, Cu<sub>20</sub>Ni<sub>80</sub> and Cu<sub>45</sub>Ni<sub>55</sub> are listed in Table 1. Note that due to the dissimilar deposition conditions (mainly the deposition time, which is different, but also other parameters like the bath formulation and deposition mode), the thickness of the mesoporous Ni film was measured to be around 7  $\mu$ m, whereas those of Cu<sub>20</sub>Ni<sub>80</sub> and Cu<sub>45</sub>Ni<sub>55</sub> were approximately 600 and 1  $\mu$ m, respectively. Al<sub>2</sub>O<sub>3</sub> nanolayers were deposited by ALD onto the previously

electrodeposited porous metallic films in a Cambridge Nanotech Savannah 100 reactor in exposure mode. The Al<sub>2</sub>O<sub>3</sub> coatings were produced by alternate pulsing of trimethylaluminum (TMA) and ozone (O<sub>3</sub>) at a deposition temperature of 100-200°C.

**Table 1.** Optimized electrodeposition parameters for the mesoporous Ni, Cu<sub>20</sub>Ni<sub>80</sub> and Cu<sub>45</sub>Ni<sub>55</sub> films.

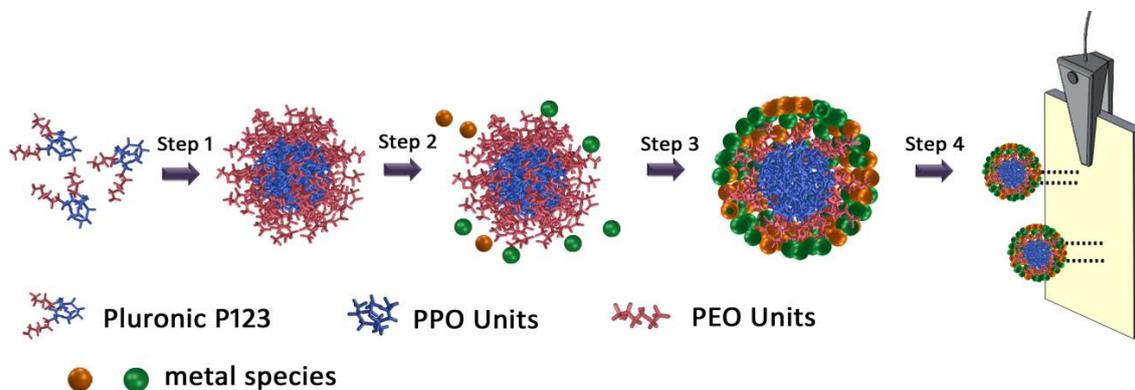

Scanning electron microscopy (SEM) images and energy-dispersive X-ray spectroscopy (EDX) analyses were acquired using a Zeiss Merlin microscope operated at 3 kV and 15 kV, respectively. Transmission electron microscopy (TEM) and scanning transmission electron microscopy (STEM)-EDX analyses were performed on a Tecnai F20 HRTEM /STEM microscope operated at 200 kV. Cross sectional specimens were prepared by embedding the films in EPON<sup>TM</sup> epoxy resin. Subsequently, a very thin slide was cut using a microtome apparatus and placed onto a carbon-coated Cu TEM grid.  $\theta/2\theta$  X-ray diffraction (XRD) patterns of the different samples were recorded on a Philips X'Pert diffractometer with a pixel<sup>1D</sup> detector in the 42-54°  $2\theta$  range (step size = 0.026°, total time = 1200 s) using Cu  $K_{\alpha}$  radiation ( $\lambda = 0.154178 \text{ nm}$ ). The crystallographic structural parameters, such as crystallite sizes, microstrains, lattice

parameter, and stacking fault probability were evaluated by fitting the full XRD patterns using the Materials Analysis Using Diffraction (MAUD) Rietveld refinement program [31,32]. Hysteresis loops were recorded at room temperature in a vibrating sample magnetometer (VSM) from Micro Sense (LOT-Quantum Design), with a maximum applied magnetic field of 4500 Oe. The loops were normalized to  $\text{emu g}^{-1}$  using the amount of material deposited as determined by coupled plasma optical emission spectroscopy (ICP-OES, model optima 4300DV). For this purpose, the films were digested in concentrated nitric acid solution at room temperature and further diluted to 1%  $\text{HNO}_3$ .

### **3. Results and Discussion**

Nanoporous Ni,  $\text{Cu}_{20}\text{Ni}_{80}$  and  $\text{Cu}_{45}\text{Ni}_{55}$  (at. %) films were electrodeposited from an aqueous solution containing the metal salts and the non-ionic, amphiphilic poly(ethylene oxide)-block-poly(propylene oxide)-block-poly(ethylene oxide) (PEO-PPO-PEO) tri-block co-polymer (Pluronic®P-123) (Table 1). In a typical preparation, the P-123 slurry was mixed manually using a glass rod upon addition of the aqueous solution containing the metal salts. Mixing time of 1 hour was required to ensure the dissolved metal species were well incorporated at the outer shell of the hydrophilic domains of the micelles. Complete mixing was confirmed by the homogeneous color and transparency of the solution. An external potential or current density was applied to reduce the metallic cations, eventually forming a silvery slab of nanoporous magnetic films (Figure 1). Hence, the surface of the working electrode acted as a solid-liquid interface, where the metallic films were deposited and patterned by the surfactant-inorganic aggregates. During the electrodeposition, the metal species are thought to move toward the working electrode together with the P-123 micelles, which act as structure-directing agents. The essence of this method is thus to exploit the self-

assembly of P123 molecules into micelles which gather spontaneously at the solid-liquid interface during the synthesis of the mesoporous films.

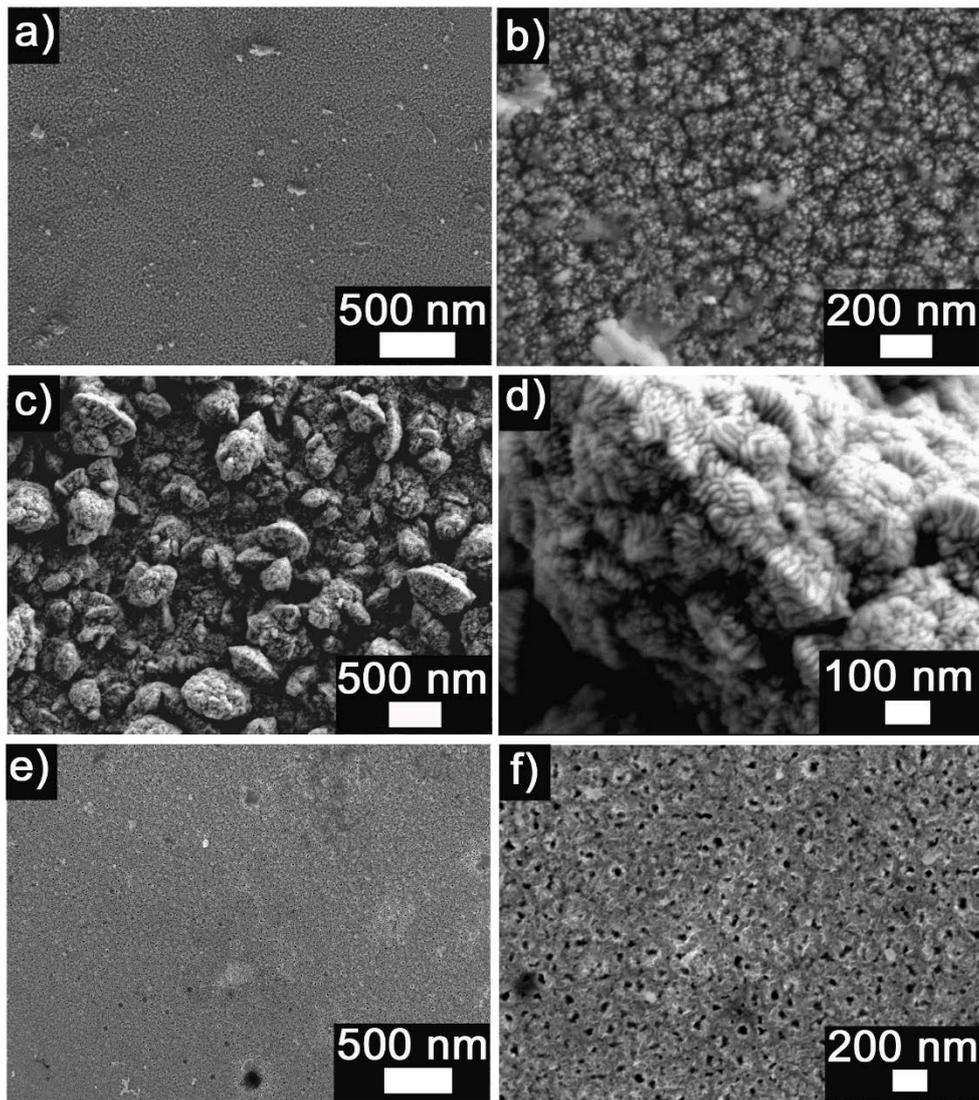

**Figure 1.** Schematic illustration of Pluronic P-123 micelle assembly strategy for the preparation of mesoporous magnetic films. Step1: stirring to form the P-123 slurry; Step 2: adding metal species to the aqueous solution; Step 3: the dissolved metal species coordinating on the PEO region of the micelles. Step 4: electrodeposition.

First, the nanoporous  $\text{Cu}_{20}\text{Ni}_{80}$  film was prepared, and its surface morphology was directly observed by SEM using secondary electrons. Shown in Figure 2a is the low-magnification top view image of the film, in which a rather homogeneous nanoporosity can be distinguished. The high-magnification SEM observation (Figure 2b) demonstrates the occurrence of a hierarchical porous architecture, consisting of aggregates of nanoparticles which leave in between a high density of nanopores, whose size ranges from 5 to 10 nm. In a dilute surfactant electrolyte, the P-123 molecules assemble into spherical micelles, but no long range organized surfactant structure exists since the concentration of the block copolymer is not high enough to form a lyotropic liquid crystal phase, as in our case.

The interaction (electrostatic, hydrogen bonding, etc.) between metal ions and surfactant assemblies is essential to tune the arrangement of the surfactant species. Therefore, using strongly acidic or basic conditions to enhance the interactions can influence the organization of inorganic polymerizing species. Namely, the decrease of the pH value of the electrolyte, from 6.25 to 4.00 (in order to increase the Cu content of the films to Cu<sub>45</sub>Ni<sub>55</sub>, see Table 1), has dramatic changes in the morphology of the coatings. Sample morphology changes from hierarchical nanoparticulated/nanoporous film to a striated patterned porous structure (Figure 2c,d). This process is probably driven by the enhanced interaction between metal ions and P-123 which may cause alignment of the pores the coalescence of micelle spheres, resulting ultimately in the formation of a corrugated mesophase. In both cases, the concentration of surfactant was set at around 0.8 wt. % which is above the critical micelle concentration (cmc) of P-123 at 25 °C [25] but lower than the threshold for lyotropic liquid formation.

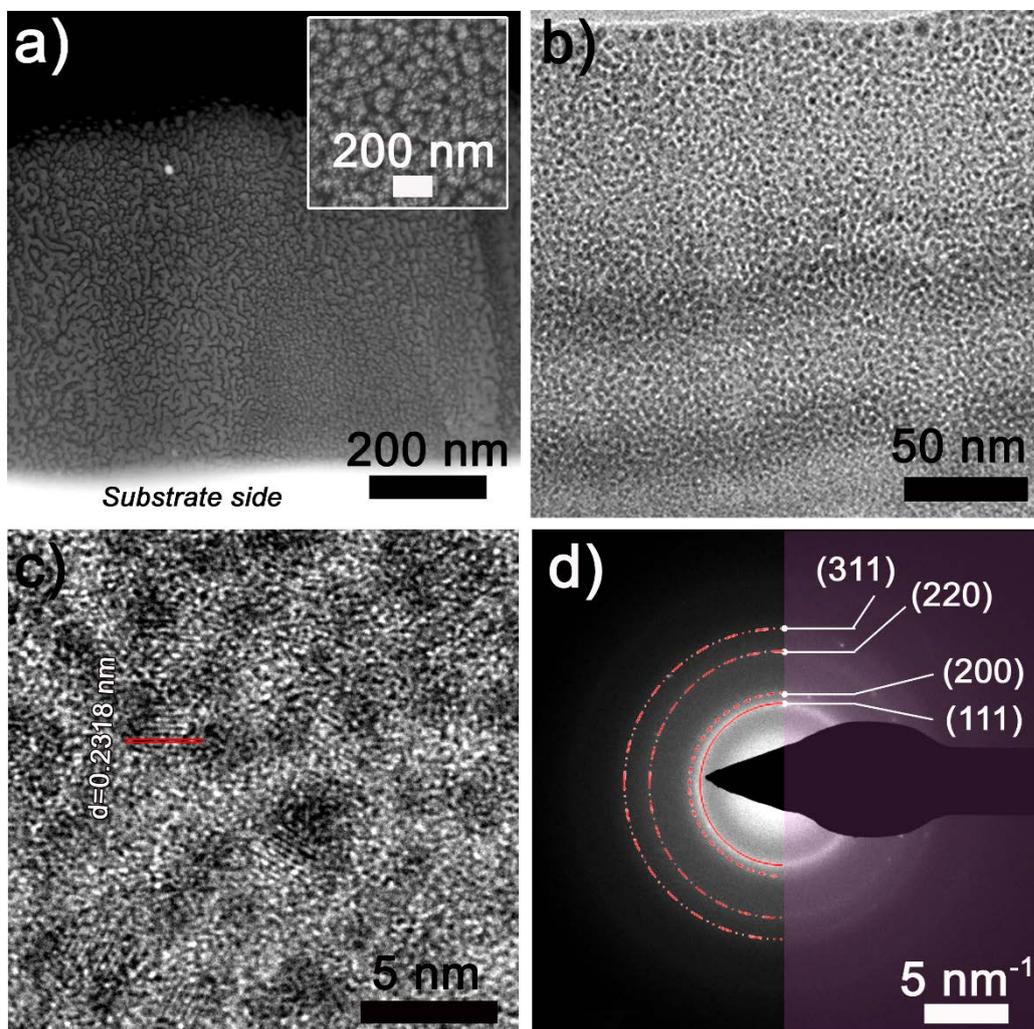

Attempts to produce Ni films with mesoporous network from the same Cu-Ni bath were proven unsuccessful. Instead, the deposition was carried out in a more predictable way by using a ternary surfactant-cosurfactant-water system. The introduction of ethanol cosurfactant to the binary surfactant/water system enriches the aqueous P-123 phase diagram [33]. The mesopore size is largely determined by the hydrophobic core of the micelle spheres. The ethanol molecules are most likely anchored to the hydroxyl groups (-OH) located at the hydrophilic-hydrophobic interface, thus increasing the apparent volume of the hydrophobic blocks rather than that of the hydrophilic blocks. Thus, the ethanol cosurfactant, which acts as a swelling agent, allows for an additional control over of the pore size [34,35].

**Figure 2.** Low and high magnification SEM images of mesoporous: a, b) Cu<sub>20</sub>Ni<sub>80</sub>; c,d) Cu<sub>45</sub>Ni<sub>55</sub>; and e,f) Ni films.

As depicted in Figure 2e, the as-deposited Ni layer is homogenous and rather free from defects such as perforations or bumps. The pore connectivity is relatively low, and many isolated pores can be observed (Figure 2e,f). High magnification observations reveal the occurrence of pores with on-top circular morphology, whose sizes range from 10 nm to 20 nm. As aforementioned, this increase in the pore size probably stems from the addition of the ethanol cosurfactant and the concomitant increase in the carbon chain

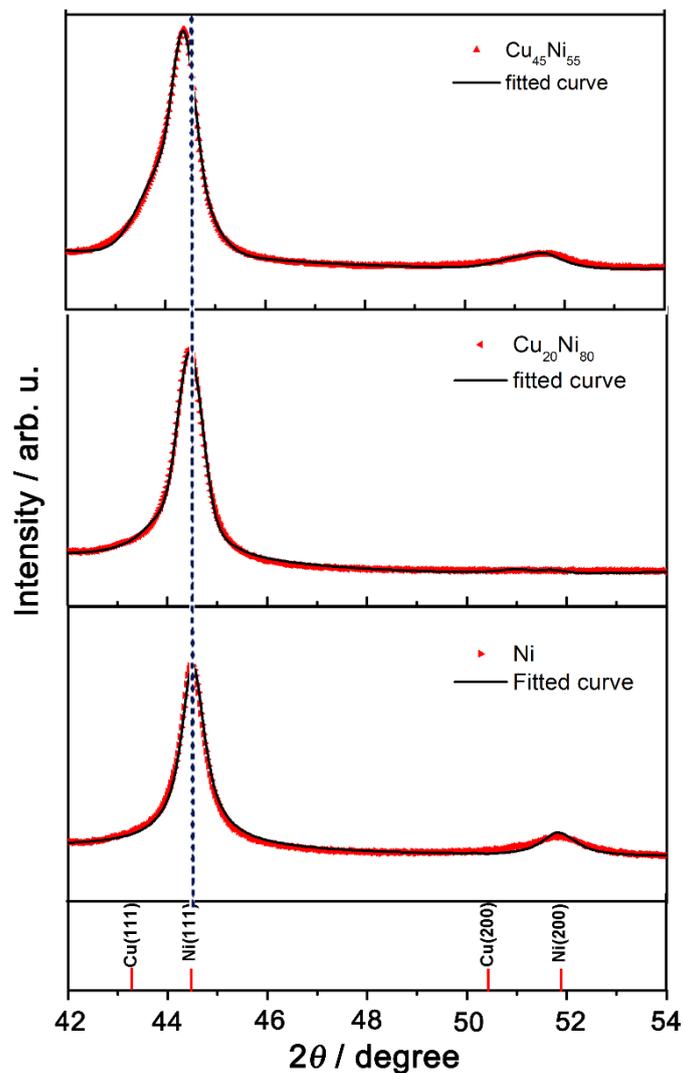

length. In all cases, the metal species were deposited uniformly on the substrates without any cracks or voids.

**Figure 3.** a) SEM, b) TEM, and c) HRTEM images of the cross-section of the mesoporous  $\text{Cu}_{20}\text{Ni}_{80}$  film. The inset in a) corresponds to the on-top SEM image, for the sake of comparison; d) corresponding SAED pattern.

To further access the inner mesoporous architecture of the films, the  $\text{Cu}_{20}\text{Ni}_{80}$  specimen was embedded in resin and sliced in order to study its cross-section morphology. The sample was fairly robust and no obvious broken pieces were observed. The typical morphology of the cross-section of this sample, observed by SEM, is shown in Figure 3a. It is worth noting that the mesoporous structure formed on the Au cathode

developed from the very initial stages of the electrodeposition process. This observation is in accordance with our preceding observations regarding the growth of pure Ni mesoporous films [34]. Freshly formed crystallites serve as nuclei seeds for the subsequent metal ions discharge, hence rendering truly nanoporous sizes. TEM images demonstrate the occurrence of open-cell porosity, with highly interconnected ligaments whose lateral size is typically around 5-7 nm (Figure 3b). The high-resolution TEM (HRTEM) image reveals that the  $\text{Cu}_{20}\text{Ni}_{80}$  frameworks are highly crystalline and the lattice fringes are visible in the entire cross-section (Figure 3c). The interplanar distance indicated on the image (0.2318 nm) matches the (111) planes of the face-centered cubic (fcc) structure. Figure 3d shows the corresponding selected area electron diffraction (SAED) pattern, for which the continuous rings indicate the formation of a polycrystalline material.

**Figure 4.**  $\theta/2\theta$  XRD patterns in the  $42^\circ$ - $54^\circ$   $2\theta$  range for ( $\blacktriangleright$ ) mesoporous Ni, ( $\blacktriangleleft$ ) mesoporous  $\text{Cu}_{20}\text{Ni}_{80}$ , ( $\blacktriangle$ ) mesoporous  $\text{Cu}_{45}\text{Ni}_{55}$ ). The computed profiles (black solid lines) obtained using the MAUD program are also shown. The bottom panel shows the theoretical lines for isotropic, pure fcc Cu and Ni.

The structure and phase composition of the obtained  $\text{Cu}_{45}\text{Ni}_{55}$ ,  $\text{Cu}_{20}\text{Ni}_{80}$  and Ni films were studied by XRD. The most intense peaks at  $44$ - $45^\circ$  match the  $2\theta$  position expected for (111) fcc Ni and Cu-Ni solid solutions, suggesting that all the samples fully crystallize in the fcc structure (space group  $\text{Fm}\bar{3}\text{m}$ , as for Cu and Ni). In the case

of  $\text{Cu}_{20}\text{Ni}_{80}$ , the (200) fcc peak, which should appear at around  $2\theta = 51\text{--}52^\circ$ , is not detected, suggesting a pronounced crystallographic texture along the (111) direction.

For both  $\text{Cu}_{45}\text{Ni}_{55}$  and  $\text{Cu}_{20}\text{Ni}_{80}$  samples, although there is no peak splitting detected, the (111) peak asymmetric broadening gives clear indication for the co-existence of Cu-rich and Ni-rich phases (i.e., two fcc solid solutions with slightly different cell parameters). In order to validate this hypothesis, the Rietveld's refinement of the XRD pattern corresponding to  $\text{Cu}_{45}\text{Ni}_{55}$  was performed in four different ways. First, the XRD pattern was fitted assuming only a single fcc solid solution without crystallographic texture (Figure S4d), however such approach cannot fit well the experimental pattern. Likewise, poor fittings were also obtained assuming a single fcc phase with (111) texture or two fcc solid solutions without texture (Figure S4b,c). Instead, a good agreement between the experimental pattern and the simulated curve was achieved upon assuming the co-existence of two fcc solutions with (111) texture (Figure S4a).

The values of cell parameters, crystallite sizes, microstrains and stacking fault probabilities of the three samples, determined by the MAUD software, are listed in Table 2. Note that the (111) fcc main reflection shifts towards higher angles as the Cu content is decreased, suggesting an overall reduction of the lattice cell parameter (which is expectable, since the lattice constant of Ni is lower than that of Cu, and Cu-Ni alloys typically obey the Vegard's law [36]). Crystallite sizes for both Ni-rich and Cu-rich solid solution phases in the Cu-Ni films are kept below 100 nm, while a value greater than 150 nm is obtained for the pure Ni film which cannot be resolved by line profile analysis [37]. The addition of ethanol to the Ni plating bath lowers the dielectric constant. The decrease of conductivity of the plating solution together with the overall different bath composition induces the observed changes in crystallite size. Interestingly,

particularly for the Cu-Ni mesoporous films, the crystallite size is considerably larger than the width of the pore walls, suggesting that several nanopores are contained inside coherently diffracting domains (i.e., the films comprises truly nanoporous crystals rather than simply being an assembly of tiny nanoparticulate clusters). The microstrains were found to be rather low in all films, in the range of  $10^{-3}$  and below. Saccharine is known to be an excellent tensile macrostress reducing agent and is thus responsible for the low microstrains (low density of dislocations in the crystals). The Rietveld refinement of the XRD patterns also includes the Warren's formalism to evaluate the stacking fault (SF) probability,  $\alpha_{SF}$ . According to the Warren's description of the SFs,  $1/\alpha_{SF}$  designates the average number of planes between two consecutive SFs. Significant stacking fault probability was only found for pure Ni, and the value is around 0.0113 (Table 2), hence, there are ca. 88 planes between consecutive SF.

		<b>Lattice parameter / Å</b>	<b>Crystallite size / nm</b>	<b>Microstrains (<math>\pm 1.0 \times 10^{-5}</math>)</b>	<b>Stacking fault probability (<math>\pm 0.0005</math>)</b>
<b>Cu<sub>45</sub>Ni<sub>55</sub></b>	Ni-rich phase	3.5402	60±2	$3.2 \times 10^{-3}$	0.0058
	Cu-rich phase	3.5720	16±5	$2.0 \times 10^{-4}$	–
<b>Cu<sub>20</sub>Ni<sub>80</sub></b>	Phase richer in Ni	3.5383	74±2	$3.2 \times 10^{-3}$	0.0067
	Phase less rich in Ni	3.5574	14±2	$1.4 \times 10^{-4}$	–
<b>Ni</b>		3.5298	> 150	$8.7 \times 10^{-4}$	0.0113

**Table 2.** Crystallographic structural parameters obtained after Rietveld's refinement of the XRD patterns of Cu<sub>45</sub>Ni<sub>55</sub>, Cu<sub>20</sub>Ni<sub>80</sub> and Ni mesoporous films.

The hysteresis loops of the nanoporous Cu-Ni and Ni films are shown in Figure 5. The highest value of saturation magnetization,  $M_S$ , corresponds to pure Ni while

$\text{Cu}_{45}\text{Ni}_{55}$  and  $\text{Cu}_{20}\text{Ni}_{80}$  films exhibit lower  $M_S$ . Interestingly, a constriction is observed in the central part of the  $\text{Cu}_{20}\text{Ni}_{80}$  hysteresis loop, suggesting the presence of two magnetic phases in this sample. Taking into account the results from XRD, these two phases could be ascribed to the two fcc solid solutions indicated in Table 1. Actually, according to the Vegard's law, the two solid solutions for the  $\text{Cu}_{20}\text{Ni}_{80}$  sample presumably contain about 85 at. % and 60 at. % Ni [36], hence both could show a ferromagnetic response (since the threshold for ferromagnetic behavior in Cu-Ni alloys at room temperature is indeed around 60 at. % [36]). The  $\text{Cu}_{45}\text{Ni}_{55}$  film does not show such narrowing of the hysteresis, indicating the presence of a single magnetic phase. In this case, according to the Vegard's law, the Ni-rich solid solution would contain approximately 70 at. % Ni, whereas the Cu-rich phase would contain only 20 at.% Ni, hence being non-magnetic. Also remarkably is the fact that the loop corresponding to  $\text{Cu}_{20}\text{Ni}_{80}$  shows a higher remanence-to-saturation magnetization ratio (i.e., a large squareness,  $M_R/M_S$ ). This is probably due to the in-plane shape anisotropy of this film, which is more textured than the other samples and effectively fully magnetic (i.e., consisting mainly of exchange coupled ferromagnetic regions). The reduction of  $M_R/M_S$  for the  $\text{Cu}_{45}\text{Ni}_{55}$  film is an indication of a lower magnetic shape anisotropy in agreement with a more polycrystalline phase (see Figure 4). This reduction of shape anisotropy is consistent with the former assumption that this film is made of Ni-rich ferromagnetic clusters embedded in a non-magnetic Cu-rich matrix (i.e., a “discontinuous” magnetic structure). This non-connected magnetic structure yields to an overall decreased exchange interactions between ferromagnetic counterparts, explaining the enhanced coercivity of the  $\text{Cu}_{45}\text{Ni}_{55}$  sample with respect to the Ni film since exchange interactions are usually in detriment of the coercivity [38]. Finally, the  $M_R/M_S$  value for pure Ni is also relatively low, but this could be anticipated due to its much larger thickness (7  $\mu\text{m}$ ,

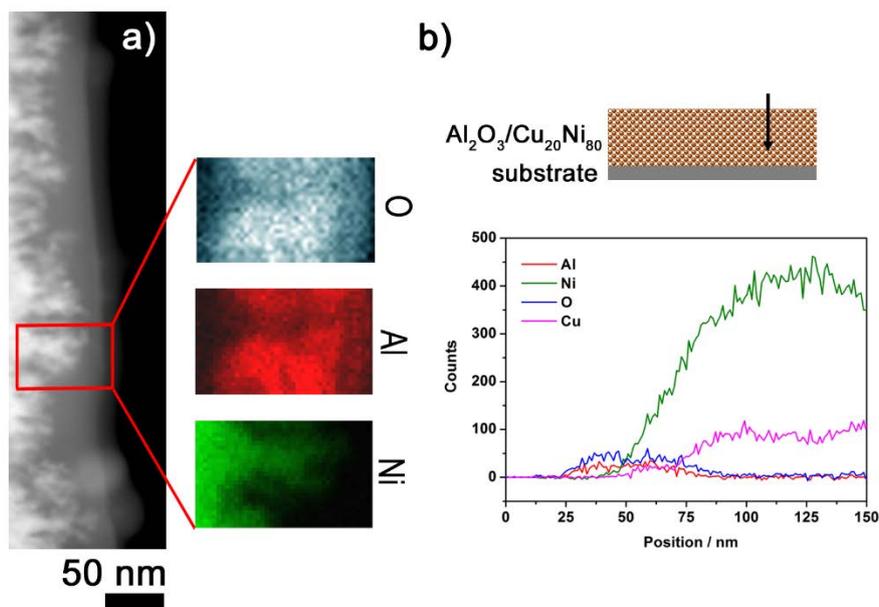

as opposed to the 600-700 nm thickness of the Cu-Ni films) and consequently lower magnetic shape anisotropy.

**Figure 5.** Room temperature hysteresis loops corresponding to Ni,  $\text{Cu}_{20}\text{Ni}_{80}$  and  $\text{Cu}_{45}\text{Ni}_{55}$  mesoporous films.

Mesoporous materials provide well-controlled nanosized environments where other materials with dissimilar chemical and physical properties can be hosted, leading to “nano-in-meso” multiphase nanocomposites. In this work,  $\text{Al}_2\text{O}_3$ , which is the most widely studied material of those prepared by ALD, was chosen to coat and fill the pores of the  $\text{Cu}_{20}\text{Ni}_{80}$  films owing to their high-quality mesoporous morphology. A  $\text{Cu}_{20}\text{Ni}_{80}/\text{Al}_2\text{O}_3$  specimen was prepared for cross-sectional imaging to assess the quality of the oxide nanocoating. After the ALD process, as shown in the STEM image (Figure 6a), the  $\text{Cu}_{20}\text{Ni}_{80}$  alloy, featuring a brighter contrast, is covered by a darker-contrast

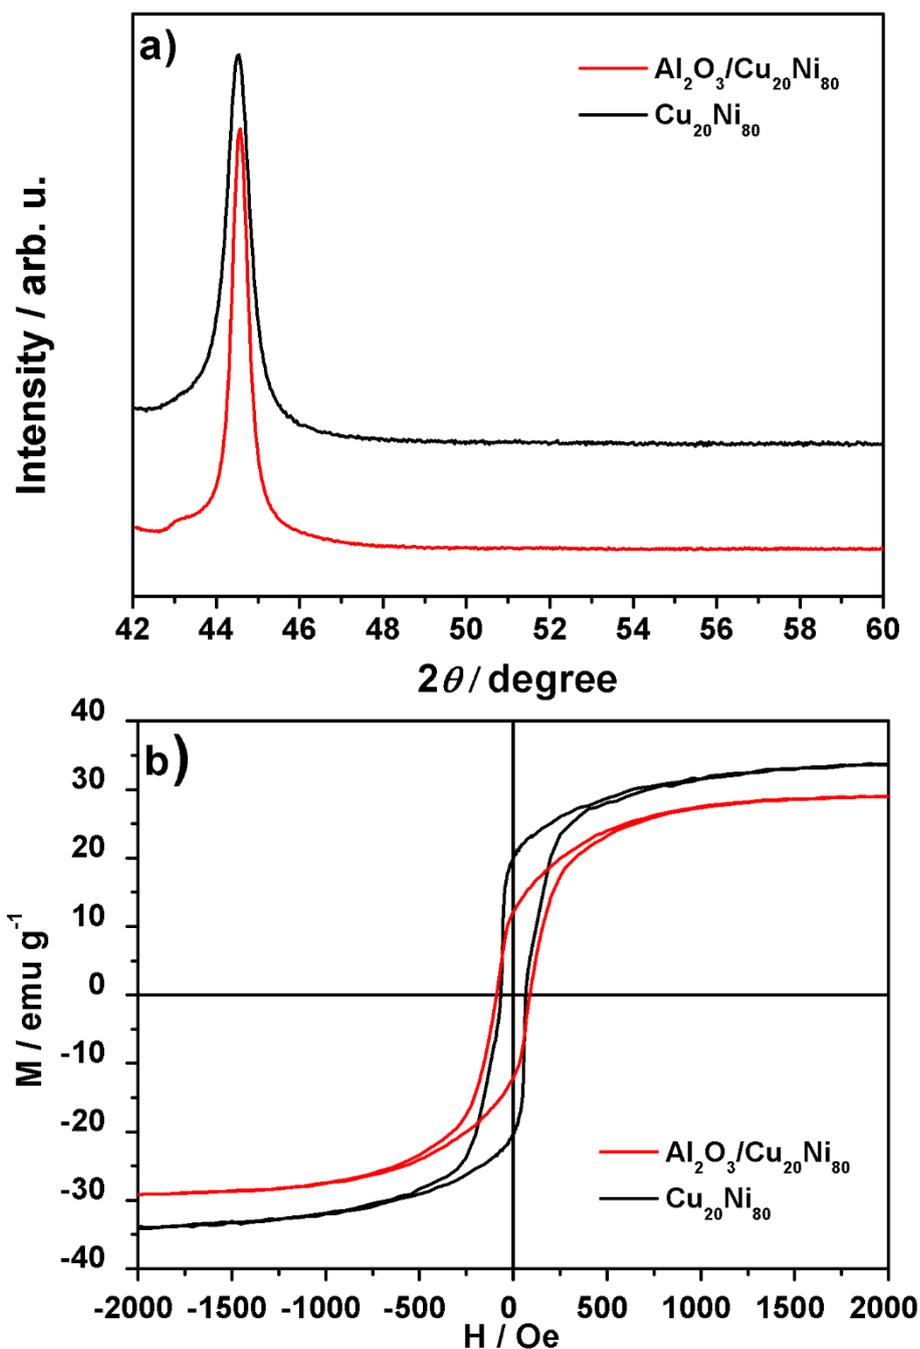

layer at the uttermost surface. The composition profile across the interface was determined by STEM-EDX elemental distribution mapping. The analysis reveals that the local distribution of Al (in red) and Ni (in green) elements is well-distinguished and that the irregular border between the two elemental maps follows the surface geometry, hence pointing to a conformal coating of the  $\text{Al}_2\text{O}_3$ . However, there is not such a clear compositional distinction between the O and Ni regions but, instead, they co-exist within a few nanometers interval. This was further proved by performing a STEM-EDX line scan analysis (Figure 6b). When the electron beam was swept from the outer upper surface of the sample towards the inner part of the material (vertical arrow in Figure 6a), the Al and O signals first appear at 10 nm from the starting point and vanish at approximately 80 nm. The Cu and Ni signals monotonically increase from around 31 nm, suggesting that the thickness of the  $\text{Al}_2\text{O}_3$  coating is about 21 nm. Hence, there is not an abrupt switch in composition but rather the four elements are present within a distance of about 50 nm from the upper surface. Therefore, it is conjectured that the outermost surface of mesoporous CuNi films got slightly oxidized during the ALD process, which is plausible bearing in mind that such treatments are performed under the presence of an  $\text{O}_3$  atmosphere. Ni-oxide, Cu-oxide and some mixed  $(\text{Al,Cu,Ni})_x\text{O}_y$  phases may exist at this interval region.

**Figure 6.** a) STEM image and EDX elemental distribution of O, Al and Ni in the interfacial area enclosed within the red rectangle; b) linear STEM-EDX analysis across the interface between  $\text{Cu}_{20}\text{Ni}_{80}$  and  $\text{Al}_2\text{O}_3$ , as indicated by the arrow in panel a).

XRD patterns were recorded to determine the formation of oxidized Cu-Ni phases and to assess whether the ALD treatments could have induced further phase separation, as previously reported in fully-dense Cu-Ni films subject to annealing treatments [39]. As depicted in Figure 7a, a small peak appears after ALD at around  $2\theta = 43^\circ$ , which can be ascribed to the Cu- or Ni-oxide. However, no obvious change of the (111) fcc reflections is observed (no peak splitting or further asymmetric shape), suggesting that the Cu-Ni mesoporous films can withstand the ALD process to a great extent from both morphological and crystallographic aspects. Only a narrowing of the (111) peak occurs, which is indicative of grain growth and reduction of residual tensions caused by the annealing process which accompanies the ALD process

(crystallite size after the ALD treatment is larger than 150 nm and cannot be resolved by X-ray line profile analysis, as evaluated using MAUD). No peaks corresponding to crystalline Al<sub>2</sub>O<sub>3</sub> are observed in the measured  $2\theta$  range. This is in agreement with the formation of amorphous Al<sub>2</sub>O<sub>3</sub> by ALD, as previously reported in the literature when similar ALD conditions are employed [30]. Finally, due to the slight oxidation that takes place during ALD, the saturation magnetization is found to decrease (Figure 7b) but only by 15%, hence a clear ferromagnetic response is preserved.

**Figure 7.** a) XRD patterns and b) room temperature hysteresis loops of mesoporous  $\text{Cu}_{20}\text{Ni}_{80}$  and  $\text{Al}_2\text{O}_3@ \text{Cu}_{20}\text{Ni}_{80}$  composite films.

## Conclusions

This work demonstrates the possibility to grow Ni and Cu-Ni nanoporous metallic films, with highly tunable porous architectures, compositions and magnetic properties, by micelle assisted electrodeposition using a tri-block copolymer as

surfactant. The as-prepared films exhibit phase separation (i.e., formation of fcc solid solutions with different Ni:Cu atomic ratios, as revealed by XRD) which, for the  $\text{Cu}_{20}\text{Ni}_{80}$  alloy, renders hysteresis loops with more than one magnetic contribution. The electrodeposited nanoporous films can be subsequently coated with  $\text{Al}_2\text{O}_3$  nanolayers by atomic layer deposition. Some surface oxidation occurs during the ALD process but this does not destroy the magnetic properties, hence allowing the formation of multiphase metal-ceramic nanocomposites with magnetic characteristics. In turn, the ALD process does not cause further crystallographic phase separation in the films. These results are technologically relevant since this type of structure/composition-engineered nanoporous films could find applications in magnetic micro/nano-electromechanical systems (MEMS/NEMS), voltage-driven magnetic actuators or, in the case of the metal-ceramic nanocomposites, as coatings with enhanced mechanical properties.
