ABSTRACT

Four conformers of the *n*-propyl-substituted Criegee intermediate, CH₃CH₂CH₂CHOO, named also *n*-butyraldehyde oxide have been observed by Fourier transform microwave spectroscopy. The transient species was produced using a pulsed electric discharge of a gas mixture of 1,1-diodobutane/O₂ diluted in Ar or Ne. The observation of only *syn* species is in contrast to the results of other previous studies of alkyl-substituted Criegee intermediates, in particular those for the structural isomers, isobutyraldehyde oxide ((CH₃)₂CHCHOO) and methyl-ethyl-ketone oxide (C₂H₅C(CH₃)OO), for which *syn* and *anti* species have been observed coexisting in the gas phase.

INTRODUCTION

Carbonyl oxides are important intermediates in the ozonolysis reaction of alkenes under atmospheric conditions.¹ Their formation is attributed to ring-opening of primary ozonides (POZ) formed directly by the 1,3-cycloaddition reaction of ozone across the olefinic bond. Aldehydes and ketones are formed as co-products in these reactions. The simplest carbonyl oxide named formaldehyde oxide, CH₂OO, is also known as the Criegee intermediate (CI), after Rudolf Criegee who first proposed pathways for carbonyl oxide formation in alkene ozonolysis.² Although the formation mechanism of carbonyl oxides was known since 1949, CIs and their reactivity could not be studied experimentally because of their short lifespan and lack of direct precursors. As a result, experimental data for CIs such as their rate coefficients were often determined indirectly with several assumptions and high uncertainties. However, Taatjes *et al.*³ in 2008 generated the simplest CI, CH₂OO, using photolysis of CH₂I₂ in O₂. This method has been demonstrated as an efficient route to the formation of the simplest CI with yields high enough to perform direct kinetic or spectroscopic measurements.⁴ Making use of this method to generate CH₂OO, several spectroscopic studies, including ultraviolet experiments,⁵⁻⁸ infrared absorption spectroscopy,⁹ Fourier transform microwave experiments¹⁰⁻¹² and millimeter wave measurements,¹³ have been devoted to characterize the structure and reactivity of this species in the gas phase. Analogous routes have been used to synthesize larger CIs, such as alkyl-derivatives.¹⁴⁻¹⁵ Consequently it has stimulated active research on these important species making it an exciting field of research with many scientific publications every year.

The atmospheric significance of CIs has been discussed for decades, and such compounds are thought to play important roles in atmospheric chemistry due to their high reactivity. Significant amounts of CIs are consumed in the atmosphere by reactions with scavengers, such as organic acids, aldehydes, SO₂, HO_x, H₂O, O₃, and NO_x, and with themselves,¹⁶⁻¹⁸ leading to the formation of secondary organic aerosols.¹⁶ The kinetics of these reactions have been deeply investigated and a strong structure dependence has been revealed.¹⁹ Alkyl-substituted CIs, formed in the ozonolysis of large alkenes, display conformational isomerism due to the presence of distinct substituent groups in their structure. In the simplest cases, such as acetaldehyde oxide, CH₃CHOO, two different configurations are possible, *syn* and *anti*, which show very different reactivities. For instance, the rate coefficients of the unimolecular decomposition of *syn*-CH₃CHOO is on the order of 10² s⁻¹ at 298 K²⁰ while for the *anti*-CH₃CHOO the measured values indicate that the self-reaction is much slower.^{21,22} In contrast, *anti*-CH₃CHOO is substantially more reactive toward water than *syn*-CH₃CHOO.^{23,24} In the cases of larger CIs the number of possible conformers increases. This is the case of C₂H₅CHOO where the ethyl part confers flexibility to the molecular system and extra conformations can be adopted. In fact, the

observation of four different species of $\text{C}_2\text{H}_5\text{CHOO}$ has been reported recently.^{25,26} Understanding of the reactivity of CIs requests the knowledge of their structural features. Thus, investigations of the intrinsic conformational preferences of these important atmospheric species constitute the first scenario.

In the present work we report the conformational investigation of the *n*-butyraldehyde oxide ($\text{C}_3\text{H}_7\text{CHOO}$, denoted in this work as NPCI) using Fourier-transform microwave (FTMW) spectroscopy. NPCI has two other structural isomers; isobutyraldehyde oxide ($((\text{CH}_3)_2\text{CHCHOO})$) and methyl-ethyl-ketone oxide ($(\text{C}_2\text{H}_5\text{C}(\text{CH}_3)\text{OO})$), which have been investigated in our laboratory in an attempt to carry out a systematic conformational study.²⁶⁻²⁸ For isobutyraldehyde oxide and methyl-ethyl-ketone oxide three and four different conformers, respectively, were observed in the gas phase including *syn*- and *anti*-isomers. The present study will reveal the effect of a larger alkyl-chain for the conformational preferences in *n*-butyraldehyde oxide, compared to other substituents with the same number of carbons but small chain-length.

MOLECULAR ORBITAL CALCULATIONS

Initial searches for minimum energy structures for the NPCI were conducted using the B3LYP/cc-pVTZ level of theory. The different conformations found were then optimized at the CCSD/cc-pVTZ level of theory (geometries are shown in Table SI of Supplementary Material) to ascertain their relative stabilities as well as the rotational parameters necessary to predict rotational transition frequencies before the spectral survey. Vibrational frequency calculations at the CCSD/cc-pVTZ level of theory were carried out to provide the Gibbs free energies for the conformers that were confirmed to be local minima in the potential energy surface by checking that their Hessian matrix did not have any imaginary eigenvalues. All the calculations were carried out using the Molpro 2012.1 *ab initio* program package.²⁹ A total of nine conformers (see Figure 1), four *syn* and five *anti*, were found in an energy window of 1400 cm^{-1} . The relative energies of the conformers are listed in Table 1, and molecular properties relevant for our rotational studies, namely rotational constants and dipole moment components, are shown in Table 2 and Table SII of the Supplementary Material for the *syn* and the *anti* conformers, respectively.

EXPERIMENTAL

The experimental measurements were conducted using a Balle-Flygare narrow-band type Fourier-transform microwave (FTMW) spectrometer operating in the frequency region of 4-40 GHz.³⁰ The short-lived species, was produced in a supersonic expansion by a pulsed electric

discharge of a gas mixture of 1,1-diiodobutane, which was synthesized using the method outlined below, and oxygen heavily diluted in argon or neon gas. 1,1-diiodobutane³¹ was prepared on a 0.1 mol scale using the synthesis of Friedrich *et al.*³² for 1,1-diiodoethane but starting from butyraldehyde. The product was purified by distillation *in vacuo* (bp_{0.1}: 47°C) and obtained in a 46 % yield.

The mixture of gases, 2% O₂ and 98% Ar or Ne, with the total pressure of 1.5 atm was passed through a container filled with liquid 1,1-diiodobutane in order to introduce the precursor molecules with a sufficient partial pressure. The gas mixture (1,1-diiodobutane, O₂ and Ar or Ne) was flowed through a pulsed-solenoid valve that is accommodated in the backside of one of the cavity mirrors and aligned parallel to the optical axis of the resonator. A pulsed voltage of 800 V with a duration of 450 μ s was applied between two stainless steel electrodes attached at the exit of the nozzle of the pulsed valve,³³ resulting in an electric discharge synchronized with the gas expansion. During the experiment, the pressure inside the vacuum chamber equipped with the cavity was kept at 6.0×10^{-5} Torr with a pulsed valve operated at a repetition rate of 10 Hz. The resulting products generated in the discharge were supersonically expanded, rapidly cooled to a rotational temperature of ~ 2.5 K between the two mirrors of the Fabry–Pérot resonator, and then probed by Fourier-transform microwave spectroscopy. MW-MW double-resonance techniques³⁴ were also used for observing pure rotational transitions and confirming the assignments of those observed by FTMW spectroscopy.

RESULTS

Due to the large number of plausible populated conformers of NPCI a wide frequency region was scanned, the chosen region was from 10 to 16 GHz due to the better performance of the spectrometer, to have an overall view of the NPCI rotational spectrum. A great number of rotational transitions were observed and most of them were confirmed as discharge products by repeating the scans in absence of electric discharge. The frequencies of the most intense lines were analyzed in the first attempt, trying to assign any of the *syn* species, predicted more stable than the *anti* ones. We assigned four different species using these intense lines, but the sets of the rotational constants were completely different from those predicted for the *syn* or *anti* conformers of NPCI. Finally they were assigned as the four conformers of *n*-butanal, which has been previously identified in the gas phase by Hotopp *et al.*³⁵

After removing all the lines of the four conformers of *n*-butanal, several weaker lines still remain unassigned. All these lines appear as single lines without any fine or hyperfine structure associated. The analysis of these lines provided the assignment of other four different species. For all the detected conformers *a*- and *b*-type rotational transitions were observed, and in

addition *c*-type transitions were measured for one of them, which finally was identified as the conformer *syn*3. The other three observed species were *syn*1, *syn*2 and *syn*4. The experimental rotational constants for these four conformers were determined by least-squares fits of the transition frequencies (Tables SIII-SVI of Supplementary Material) using Watson's A-reduced $^1\Sigma$ Hamiltonian,³⁶ and the results are summarized in Table 3. The identification could be easily achieved by comparing the experimentally determined spectroscopic constants with those predicted *ab initio*. The calculated constants in Table 2 show maximum deviations from experimental values of 1.4 %, indicating that the calculated *ab initio* geometries are fairly accurate.

After surveying the rotational transitions of the *syn* conformers much weaker rotational transitions prevail unassigned. They may belong to the *anti* conformers which are predicted to be about 1000-1300 cm⁻¹ less stable than the *syn*-species. Several attempts to fit these remaining lines to any of the *anti* conformers were carried out, but they prevail unassigned. Furthermore, exhaustive additional searches were done to look for spectral signatures of *anti* conformers but no lines belonging to any other conformer were observed in the spectrum.

All these mentioned experiments were done using the gas mixture of 2% O₂ diluted in Ar. In the second part of the experiments we changed Ar with Ne as the carrier gas, repeating all the frequency scans. In a previous study²⁶ we found significant differences when Ar or Ne was chosen as the carrier gas due to their different cooling efficiency in supersonic expansions.^{37,38} In fact, an Ar-seeded expansion is expected to favor conversion of higher energy conformers to lower ones, while higher energy species will survive in a Ne-seeded expansion. Although *syn*- and *anti*-species cannot interconvert with each other, the presence of Ar or Ne could affect to the formation processes of both species. Unfortunately, the new scans did not show any differences with those performed with Ar as the seeding gas including the relative intensities between the *n*-butanal and NPCI, and those among the four conformers of NPCI.

DISCUSSION

As shown in previous studies of alkyl-substituted Criegee intermediates, such as CH₃CHOO,^{14,39} C₂H₅CHOO²⁵ and (CH₃)₂CHCHOO²⁶ the *syn* conformers are predicted to be the preferred configurations. This major stability can be ascribed to the attractive interaction between the terminal oxygen atom and the protons of the closer carbon atom of the alkyl moiety. The terminal oxygen has three lone-pairs in a zwitterionic canonical structure, C_nH_mCH=O⁺–O[–], which is considered to contribute significantly to the ground state electronic structure at least in CH₂OO.¹⁰ Two of the three lone-pairs, occupying the valence *sp*³ orbital, seem to be interacting with the protons of the –CH₂– protons in the case of *syn* conformers. This stabilizing interaction

cannot occur in any of the *anti* conformers of NPCI, hence their lower stability compared to the *syn* conformers. The non observation of *anti* conformers for NPCI is in contrast with the results of all the previous studies of alkyl-substituted CIs,^{14,25-27,39} in which both *syn* and *anti* conformations were detected coexisting in the gas phase, even when the energetic difference between them was similar to that for NPCI (around 1000 cm⁻¹). The concentration *syn/anti* ratios were found to be around 5 for these alkyl-substituted CIs, such as CH₃CHOO^{14,39} and C₂H₅CHOO,²⁵ in accordance with the relative energy predictions assuming the temperature of 1100 K. Attending to our calculations *anti* species of NPCI should be present in our supersonic expansion in detectable amounts but no traces of these conformers were found. As shown before, the four conformers of *n*-butanal³⁵ were also produced in our experiment in a significant amount. In the above mentioned studies of alkyl-substituted CIs, where similar precursors were used, we observed their corresponding aldehydes formed as secondary products in the electric discharge in addition to the CIs. For example, in the case of C₂H₅CHOO²⁵ and (CH₃)₂CHCHOO²⁶ studies, we observed the rotational spectra of propionaldehyde and isobutyraldehyde, respectively. The main difference with the present case is the abundances of these aldehydes. While for C₂H₅CHOO and (CH₃)₂CHCHOO the abundances of the aldehydes were ~20% lower than those for the CIs, in the NPCI experiment the most intense lines correspond to *n*-butanal, for which concentration has been estimated to be 4-5 times larger than that for NPCI conformers. The formation of these aldehydes, including *n*-butanal, from the corresponding CIs only requires the release of the terminal oxygen. Thus, the high concentration of *n*-butanal in our experiment can be associated with a faster decomposition of NPCI, compared to other CIs. Probably, the reaction to produce *n*-butanal from NPCI is more rapid for the *anti* conformers, which decreases its concentration in the gas phase and consequently inhibit its observation.

As mentioned in the introduction NPCI is a C₄ family CI with two other structural isomers; (CH₃)₂CHCHOO²⁶ and C₂H₅C(CH₃)OO²⁷ which have been recently investigated in our lab as well. Three conformers were observed in the case of (CH₃)₂CHCHOO among the four conformers predicted in an energy window of ~1300 cm⁻¹, being the two *syn* species the most stable ones. The non-observation of one *anti* conformer was ascribed to an interconversion process to the other *anti* conformer taking place during the supersonic expansion. The C₂H₅C(CH₃)OO case is slightly different from NPCI and (CH₃)₂CHCHOO because C₂H₅C(CH₃)OO is a doubly-substituted CI and the energy differences between the plausible conformers are much smaller. Two *syn* and two *anti* species were predicted with energy difference within 200 cm⁻¹, and all of them were detected coexisting in the gas phase. In contrast, the length of the alkyl chain makes NPCI to have a larger number of energetically

accessible conformers, up to nine with energies below 1400 cm^{-1} , and unlike the cases for $(\text{CH}_3)_2\text{CHCHOO}$ and $\text{C}_2\text{H}_5\text{C}(\text{CH}_3)\text{OO}$ only the *syn* species, predicted as most stable ones, have been detected. Therefore, the conformational richness of NPCI can be another fact that restricted our observations only to the *syn* species, since the number of possible states is larger, compared to other studied systems, making the intensity of the spectral transitions become smaller.

The alkyl-substituent of the NPCI system has a longer chain, compared to those of other CIs studied so far, and this chain can provide larger cross sections in collisional environment at the first stages of the supersonic expansion. That means that the effective temperature of the system will be lower than that for other CIs with smaller alkyl-substituents. For related systems such as CH_3CHOO ,^{14,39} $\text{C}_2\text{H}_5\text{CHOO}$ ²⁵ and $\text{C}_2\text{H}_5\text{C}(\text{CH}_3)\text{OO}$ ²⁷ the temperature at which the reaction to form the CIs occurs was estimated to be around 1100 K. This value explains approximately the relative abundances of the *syn* and *anti* species in such cases. In contrast, for NPCI the effective temperature seems to be much lower due to effect of the alkyl chain. In Table 4, the relative populations for all the conformers at 300 K and 1100 K calculated using the Gibbs free energies from Table 1, are shown. As can be seen, at 1100 K the estimated population of the *anti* conformers is high enough to be observed in our experiment, in fact, for some conformers the predicted abundances are comparable to that for *syn4* species. At lower temperatures, the population of the higher energy conformers, the *anti* ones, is almost negligible as shown in Table 4, where the populations were calculated at 300 K.

In order to check the relative concentration of the *syn* conformers, the experimental relative populations of the observed conformers in the supersonic expansion were estimated by relative intensity measurements of the same rotational transitions. It is assumed that the supersonic expansion brings all conformers to their lowest vibrational state and that the intensity of the rotational transition is proportional to the number density of each conformer and the value of the corresponding component of the dipole moment, $N_i \cdot \mu_i$. N_i corresponds to the molecules populating all the vibrational states of a given conformer at the first stages of the expansion, and μ_i is the corresponding electric dipole moment component. From these measurements we found an approximate population ratio depicted in Table 4, with *syn3* conformer being the most abundant species. These results agree better with the calculations at 300 K but conformers *syn2* and *syn3* show higher populations than expected. It should be noted that conformers *syn1*, *syn3* and *syn4* have their equivalent (isoenergetic) counterparts differing in the sign of the $\angle\text{CCCC}$ dihedral angle. However, this is not the case for *syn2* because of the planarity of its backbone. The ratios between the pairs of conformers *syn1/syn4* and *syn2/syn3* are almost the same for the experimental and theoretical cases. This fact can be related to the structural arrangement of the

alkyl-substituent. The relative disposition adopted by the $\angle\text{OCCC}$ dihedral angle for *syn2* and *syn3* conformers is a *trans* while that for *syn1* and *syn4* is *gauche*, as can be seen in the Figure 1. This arrangement can affect their different unimolecular decay to form OH radicals. For the ethyl-substituted CI, $\text{C}_2\text{H}_5\text{CHOO}$,²⁰ it has shown that conformer *syn2*, with a *gauche* arrangement for $\angle\text{OCCC}$, shows a faster unimolecular decay rate (around 30% faster) in the decomposition process to OH products than conformer *syn1*, whose arrangement for $\angle\text{OCCC}$ is *trans*. Assuming a similar behavior for the NPCI, where the *syn1/syn4* conformers decompose to OH products faster than the *syn2/syn3* conformers do, their relative conformational abundances will be changed with a smaller amount of *syn1/syn4* species, justifying the discrepancies between the theoretical and the experimental values.

As can be seen in Figure 2, none of rotational transitions for the four observed conformers of NPCI shows any splittings, such as *A/E* splittings due to the internal rotation, despite the presence of a methyl group in the molecule. In contrast, *A/E* splittings produced by the internal rotation motion of either CH_3 - or C_2H_5 - tops were observed for most of the conformers for related alkyl-substituted Criegee intermediates such as CH_3CHOO ,^{14,39} $(\text{CH}_3)_2\text{COO}$,⁴⁰ $\text{C}_2\text{H}_5\text{CHOO}$ ²⁵ and $\text{C}_2\text{H}_5\text{C}(\text{CH}_3)\text{OO}$.^{27,28} The experimentally observed values of the V_3 barrier heights for the hindered internal rotation were found to be from 399 cm^{-1} , the smaller value for *anti*- CH_3CHOO , up to 953 cm^{-1} , the larger value in the case of $\text{C}_2\text{H}_5\text{C}(\text{CH}_3)\text{OO}$, being the differences associated to steric hindrances. In this study, we estimated the V_3 methyl internal rotation barrier heights at the CCSD/cc-pVTZ level of theory for all the observed conformers of NPCI and we found them to be between $1140\text{--}1220\text{ cm}^{-1}$. These values are too high to observe any *A/E* splittings in our spectra despite the subdoppler resolution associated to our spectrometer.

CONCLUSION

The conformational behavior of the *n*-propyl-substituted Criegee intermediate ($\text{C}_3\text{H}_7\text{CHOO}$) has been investigated through FTMW spectroscopy. The C_3H_7 - alkyl chain confers high flexibility to the molecular system and the number of energetically accessible conformers increases compared to those for related systems such as the structural isomers isobutyraldehyde oxide ($(\text{CH}_3)_2\text{CHCHOO}$) and methyl-ethyl-ketone oxide ($\text{C}_2\text{H}_5\text{C}(\text{CH}_3)\text{OO}$). A total of four *syn*-conformers were observed in the rotational spectrum but no spectral signatures for any of the *anti*-conformers were found in the spectrum. This result is quite different from our previous studies for related alkyl-substituted Criegee intermediates. Three possible reasons may be contributing to the non-observation of the *anti* species; (i) that the NPCI decomposes very fast to *n*-butanal, especially the *anti*-conformers; (ii) the large number of plausible conformers

suggests that the population is distributed in many states and the individual contribution of each conformer will be lower than in other CIs with less accessible conformers and (iii) the *n*-propyl chain contributes to a lower effective temperature prior to the supersonic expansion and thus giving a lower concentration of higher energy conformers.

SUPPLEMENTARY MATERIAL

See Supplementary Material for the optimized geometries and measured transition frequencies for NPCI conformers.

^a Relative energy to that of *syn*1.

^b Relative energy to that of *syn*2.

Table 2. Theoretical spectroscopic constants for the *syn* conformers of NPCI calculated at CCSD/cc-pVTZ level.

	<i>syn</i> 1	<i>syn</i> 2	<i>syn</i> 3	<i>syn</i> 4
<i>A</i> /MHz	7466	10953	9710	6607
<i>B</i> /MHz	2033	1566	1698	2170
<i>C</i> /MHz	1761	1405	1603	2060
$ \mu_a /\text{D}$	2.8	5.1	5.8	4.1
$ \mu_b /\text{D}$	4.8	3.4	1.4	3.8
$ \mu_c /\text{D}$	0.2	0.0	1.7	1.0

Table 3. Rotational constants for the four observed conformers of NPCI.

	<i>syn1</i>	<i>syn2</i>	<i>syn3</i>	<i>syn4</i>
<i>A</i> /MHz	7544.8040(24) ^a	10932.8951(18)	9704.5022(14)	6576.2082(56)
<i>B</i> /MHz	2003.7535(20)	1564.56066(54)	1692.52342(50)	2164.77142(63)
<i>C</i> /MHz	1741.8070(20)	1404.50934(49)	1599.67713(50)	2058.97922(60)
Δ_J /kHz	1.1182(15)	0.179(33)	0.486(13)	2.5171(43)
Δ_{JK} /kHz	-6.720(90)	-1.926(32)	-5.114(71)	-17.694(59)
Δ_K /kHz	31.50(52)	-	-	53.9(11)
δ_J /kHz	0.02630(75)	0.0290(42)	-	0.0934(51)
δ_K /kHz	3.14(93)	-	11.2(25)	-
<i>N</i> ^b	16	19	16	18
σ /kHz	2.1	2.1	2.7	2.6

^a Values in parentheses denote 1 σ errors, applied to the last digit.^b Number of rotational transitions included in the fit.**Table 4.** Theoretical relative abundances for NPCI conformers calculated using the Gibbs free energies from Table 1. The experimental relative abundances found for *syn* species are also shown.

	Rel. pop. (300 K) ^a	Rel. pop. (1100 K) ^b	Rel. pop. Exp.
<i>syn1</i>	2.1	1.2	2.5
<i>syn2</i>	2.8	1.6	5.2
<i>syn3</i>	2.9	1.2	5.7
<i>syn4</i>	1.0	1.0	1.0
<i>anti1</i>	5.6x10 ⁻³	0.3	-
<i>anti2</i>	4.4x10 ⁻³	0.7	-
<i>anti3</i>	1.1x10 ⁻²	0.8	-
<i>anti4</i>	3.8x10 ⁻³	0.4	-
<i>anti5</i>	1.2x10 ⁻²	0.6	-

^a Relative populations considering ΔG energies at 300 K.^b Relative populations considering ΔG energies at 1100 K.

Figure 1. Plausible conformers of NPCI obtained from *ab initio* calculations at the CCSD/cc-pVTZ level.

Figure 2. A section of the FTMW spectrum of NPCI. The transitions marked with a circle correspond to NPCI, those signalized with an asterisk belong to *n*-butanal and those denoted with a triangle arise from non-discharge products. The rest of transitions without any marked are unidentified rotational transitions. The inset “a” corresponds to the $1_{10}-1_{01}$ rotational transition of the *cis/trans* conformer of *n*-butanal, while the “b”, “c” and “d” insets are the $4_{14}-3_{13}$, $2_{12}-1_{01}$ and $3_{12}-2_{11}$ rotational transitions of *syn3*, *syn1* and *syn4* conformers of NPCI, respectively. Each rotational transition is split into two Doppler components because the direction of the supersonic jet expansion is parallel to the standing wave in the Fabry-Pérot cavity of the spectrometer.
