ABSTRACT

Raman and transmission FTIR spectroscopic techniques have been coupled in a new homemade reactor-cell designed in a joint CSIC-UNICAEN collaboration. The set-up is easily adapted to any FTIR and fibre-coupled Raman spectrometers and gas analysis techniques. Simultaneous *operando* FTIR and Raman spectroscopic measurement allow complementary characterization of adsorbed species, reaction intermediates, and structural properties of the catalyst. This system was validated with the study of vanadium based catalysts during propane OxyDeHydrogenation (ODH). The combined use of both spectroscopies with gas analysis techniques to measure the activity contributes to the understanding of propane ODH and the identification of the role of different oxygen species bound to vanadium sites. For example, the simultaneous characterization of the catalyst under the same conditions by IR and Raman confirms that the V=O mode has the same frequency in both spectroscopies, and that bridging oxygen sites (V-O-V, V-O-Zr) present higher activity than terminal V=O bonds. These results demonstrate the high potential of the new simultaneous transmission IR-Raman *operando* rig to correlate the activity and the structure of catalysts, thus assisting the rational design of catalytic processes.

Introduction

The establishment of relationships between surface structure and performance of catalysts is indispensable to understand catalytic reaction mechanisms and deactivation phenomena, identify active phases, and rationally design more efficient catalytic materials and processes. In this sense, there has been an increasing interest in the development of characterization techniques of functional materials under real operating conditions. *In situ* and *operando* characterization has been performed with different techniques, such as IR ^{2-4, 13-17}, EPR ¹⁸⁻¹⁹, synchrotron based techniques ^{5,20-21}, Raman ^{6-8,22-30}, NMR ^{9,10}, UV-VIS ¹¹ or TEM ^{1,12}. All these works point out the high-value information obtained by simultaneously tracking catalysts structure and reactivity, and the need for more technological progress, for example in the design of high quality reaction-cells, the development of techniques for the study of interfaces, space and time-resolved spectroscopy, and, particularly, multimodal *operando* set-ups. Since each characterization technique can provide only a part of the picture, one of the present challenges is to combine different spectroscopic techniques in a single rig that provide complementary insights into catalysts behavior.

Several works report the use of different simultaneous characterization techniques to study the catalytic material and/or the reaction medium. Among these multimodal *operando* approaches, Baiker *et al.*³¹ performed a combined liquid-phase ATR-IR and XAS study during the aerobic oxidation of benzyl alcohol over Pd based catalysts. They obtained information about the particle structure/oxidation state by XAS and the surface species by ATR-IR, and

monitored the catalytic activity using FTIR spectroscopy. Weckhuysen's group³² designed a laboratory setup for combined *operando* X-ray diffraction and Raman spectroscopy of catalysts, with analysis of reaction products by gas chromatography. They used such setup to study the long-term deactivation of Co-based catalysts during Fischer-Tropsch synthesis. The same group also used XAFS, Raman and UV-Vis spectroscopies in a single experiment³³. The combination of XAS, XRD and Raman for phase speciation in water gas shift reaction catalysts has also been performed³⁴. The *operando* coupling of EPR, Raman and UV-Vis spectroscopies was reported by Bruckner³⁵. These and other examples, as those highlighted in a review by Bentrup³⁶, demonstrate how the coupling of complementary *operando* techniques in one rig results in more rational and comprehensive information, necessary for the efficient design of catalytic materials.

The combination of Raman and infrared spectroscopies is particularly convenient for supported oxides³⁷, since Raman spectroscopy reports essentially the structure of the supported phase while IR has more sensitivity to adsorbed species. Payen *et al.*³⁸ performed alternate *in situ* characterization by Raman and IR of Pd based catalysts for DeNO_x using a commercial Raman spectrometer with an IR extension (Horiba Jobin Yvon). Zhang *et al.*³⁹⁻⁴⁰ designed a home-made high-throughput reactor that combines FTIR and Raman spectroscopies. That setup has six parallel reaction channels with six Raman probes to study the catalysts, while the gas product is analysed by FTIR imaging. Urakawa⁴¹ designed a DRIFTS-Raman setup configuration that enables simultaneous IR-Raman detection with high spatial resolution in order to monitor the surface of catalysts during NO_x storage and reduction. These contributions underline the

complementarity of both spectroscopies. It should be noted, though, that the measurements are not always simultaneous, and, in many cases, IR data rely on the use of DRIFTS or ATR-IR, two precious techniques which, however, are not directly quantitative and usually have lower sensitivity than transmission, since the scattered signal can be weak, and thus more difficult to interpret. Quantitative data are nevertheless required to elucidate the catalyst role for many reactions and to properly perform spectrokinetic studies ⁴².

Thus, the present paper reports the design and validation of a novel concept of *operando* IR-Raman cell (the “IRRaman” *operando* reactor), conceived to obtain under real operating conditions, in a single experiment, with space and time consistency, transmission FTIR and Raman spectra of catalysts, coupled with online analysis of the reaction products. Therefore, information about the catalyst structure (mainly from Raman), adsorbed species (mainly from FTIR) and reactivity (from gas phase analysis) blend into a single experiment. The usefulness of this multimodal *operando* rig is demonstrated here through the study of the propane oxidative dehydrogenation (ODH) reaction over V-Zr-O catalysts. Propane ODH has been largely studied ⁴³⁻⁴⁷. Dispersed vanadia or molybdena-based catalysts are well known as active catalytic materials for this process.⁴⁵ The reaction mechanism shows that surface monomeric and polymeric species are active and participate in the formation of propyl or (iso)propoxy species as first reaction intermediates, which are usually further oxidized giving rise to CO_x in the gas phase ⁴³. The evolution of the solid catalyst during the pre-activation treatment and, afterwards, under the reaction flow is followed here with the new IRRaman *operando* reactor and correlated to the development of the adsorbed species.

Experimental section

Catalysts synthesis. Zirconium (IV) propoxide solution (Sigma-Aldrich, CAS: 23519-77-9, 70 wt. % in 1-propanol), polyvinylpyrrolidone (PVP) (Sigma-Aldrich, CAS: 9003-39-8, Mw ~1,300,000), acetylacetone (Sigma-Aldrich, CAS: 123-54-6, ≥99%), 1-propanol (Sigma-Aldrich, CAS: 71-23-8, ≥99.5%) and vanadyl acetylacetonate (Sigma-Aldrich, CAS: 3153-26-2, ≥97.0%) were used as starting materials. The catalysts were prepared by electrospinning. The synthesis of the solutions has previously been described ⁴⁸. Briefly, the starting polymer solution was prepared by dissolving 2.100 g of the zirconium fibers precursor (zirconium (IV) propoxide) and 0.317 g of PVP in 2.984 g of 1-propanol solvent with 0.450 g of acetylacetone. Then, vanadyl acetylacetonate was added to three fractions of this polymer solution to obtain final fibers with nominal vanadium mass concentrations of 2.5% (Zr-V2.5), 5.0% (Zr-V5.0) and 6.4% (Zr-V6.4). Subsequently, the three polymer solutions were vigorously stirred for 24 h at room temperature. The electrospinning equipment and procedure have also been described in previous articles ⁴⁸⁻⁴⁹. The electrospun fibers were calcined in air flow (150 mL·min⁻¹ STP) at 500 °C in a conventional tubular furnace, with a heating rate of 10 °C·min⁻¹ followed by 6 h dwell time in order to eliminate the organic part and the remaining solvent, and to stabilize the zirconia fibers. The final vanadium mass concentration obtained by XPS analysis of Zr-V2.5, Zr-V5.0 and Zr-V6.4 samples was reported to be 2.7, 4.9 and 6.0%, respectively⁴⁸⁻⁴⁹.

The “IRRaman” reactor. The IR-Raman *operando* rig was specifically designed at Laboratoire Catalyse et Spectrochimie (Caen, France), adapting a home-made

operando IR reactor-cell for self-supported wafers of ~20-30 mg and 2 cm² (the so-called "Sandwich" reactor)⁵⁰ to also host a Raman probe (Figure 1). This cell is a genuine catalytic reactor, both from the point of view of fluid dynamics⁵¹ and catalyst morphology preservation⁵². Evolutions of the "Sandwich" cell have already been developed in the past to facilitate kinetic analysis⁵¹ or to determine reaction mechanisms in photocatalysis⁵³. The adaptations made in the framework of this study (detailed in the SI) aim to continuously collect both transmission FTIR and backscattering Raman spectra from representative, close-by points of the pellet. Therefore, the cell was notably modified by replacing the two KBr windows positioned on one side of the cell by a stainless steel cylinder. Two holes were drilled in the cylinder, one to accommodate the Raman probe and another one for a dedicated small KBr window (d=4 mm) to let the IR beam pass through. Air tightness was guaranteed via Kalrez O-rings. The position of the Raman probe, and thus the distance to the pellet surface (approximately 1 mm), is adjustable to optimize the signal intensity. The pellet temperature is measured via a thermocouple placed on the sample holder to ensure proper temperature control independently of the new reactor configuration..

The cell is placed in an IR spectrometer bench (Nicolet 6700 FT-IR spectrometer equipped with a MCT/A detector) to record transmission IR spectra (64 scans/spectrum, 2 cm⁻¹ resolution). A laser (532 nm) beam generated by a Horiba Jobin Yvon Labram300 spectrometer is guided into the IRRaman reactor by an optical fiber and focused on the sample with an *ad hoc InPhotonics* Raman probe specially designed to withstand high temperatures. Raman spectra resolution was 1.5 cm⁻¹ and laser power on the sample was 5 mW. It must be noted that at the end of the experiments the pellet did not show any sign of local overheating

or preferential carbon deposit in the analysis zone of the Raman laser. The dual IR-Raman *operando* reactor was fed with controlled gas flow rate and composition, and heated for catalyst activation or reaction. Downstream the catalyst wafer, the exhaust gases are directed towards an IR gas cell, and a mass spectrometer (MS) for simultaneous on line analysis.

ODH reaction conditions. Three catalytic materials (Zr-V2.5, Zr-V5.0 and Zr-V6.4) were pressed into self-supported wafers and tested for ODH in the

IRRaman *operando* reactor. The weight of catalyst (W_{cat}) and the total volumetric gas flow (F_T) were 31.5 mg and 18.1 mL·min⁻¹, respectively, resulting in a space-time ($W_{\text{cat}}/F_{\text{C}_3\text{H}_8}$) of 0.53 g_{cat}·s·mL⁻¹_{C₃H₈}. The reaction temperature was varied from 200 to 340°C. Two different gas mixtures were used in the ODH experiments, an activation flow of 10% oxygen in argon, and a reaction flow consisting of a mixture of 20% propane and 10% oxygen in argon. Dehydrogenation (DH) experiments were also carried out without oxygen in the activation and reaction flows. Gas lines were heated at 60°C before and after the reaction-cell to pre-heat the reaction mixture and to avoid products condensation. The samples were first dehydrated by heat treatment under activation flow from room temperature to 340°C with a heating rate of 5°C·min⁻¹. After dehydration and equilibration at the selected reaction temperature, the samples were submitted to activation and reaction flows with and without oxygen in different order. The conditions were changed when the steady state was achieved.

Operando FTIR and *operando* Raman spectra of the catalysts were acquired every 2 and 4 min, respectively. Reactants and products of the gas phase were analyzed online by FTIR gas cell (one spectrum every 2 min), and mass spectrometry (one measurement every 3 s). These data provided conversion, selectivity, and TOF results, as detailed in the SI.

Results and Discussion

1) Monitoring of the pre-activation of the catalysts

Before reaction, the catalysts were dehydrated during the initial activation step. Figure 2 shows the simultaneous Raman and infrared spectra of the hydrated and dehydrated samples. The IRRaman approach allows the determination of all

the vibrational bands from 5000 cm^{-1} to 150 cm^{-1} , without the restrictions usually observed in IR spectroscopy of solids, where lattice bands absorb all the signal below ca. 1000 cm^{-1} . All samples show broad Raman bands (642, 459, 314 and 268 cm^{-1}) associated with the tetragonal phase of zirconia^{48,54}, in agreement with the XRD results (Supporting Information, Figure S1); these bands are not sensitive to hydration/dehydration (Figure 2B) and are used to normalize the intensity of the Raman spectra. The infrared bands near 1630 cm^{-1} and at 3500-3400 cm^{-1} show the presence of adsorbed water in all samples at room temperature (Figure 2A); these bands are respectively attributed to the H-O-H bending and $\nu(\text{OH})$ stretching modes⁵⁵⁻⁵⁶. The infrared signal of adsorbed water molecules increases with vanadia content and disappears upon dehydration (Figure 2A). Weak bands due to the hydroxyls on the solid are then visible around 3700 cm^{-1} . The Raman and infrared $\text{V}=\text{O}$ modes near 1020 cm^{-1} ⁵⁷⁻⁵⁸; are characteristic of molecularly dispersed vanadium oxide species⁵⁹ and blue-shift upon dehydration. Moreover, in dehydrated samples they blue-shift from 1019 to 1029 cm^{-1} as the vanadium content increases from 2.5 to 6.4% (w/w), due to a higher relative population of polyvanadates with respect to monovanadates⁵⁹. *It is important to underline the highly consistent wavenumbers observed for the $\text{V}=\text{O}$ mode in both the Raman and the infrared spectra for all vanadia loadings* (Figure 3). This implies that the cell design and the neighboring spots of analysis for IR and Raman are well-suited for the measurements in exactly the same conditions.

No additional information may be extracted from infrared spectra below 900 cm^{-1} , due to the strong absorption of zirconia support. Conversely, Raman spectroscopy does provide additional information of vanadia species in that

spectral window: the broad Raman signal in the 700-950 cm^{-1} range grows stronger with vanadium content and corresponds to V-O-V and V-O-Zr modes^{48,60}, the signal for V-O-V chains appears near 880 cm^{-1} ⁶¹, while the broad signal near 770 cm^{-1} is assigned to V-O-Zr vibrations like in ZrV_2O_7 samples^{48,62}. Since crystalline V_2O_5 presents intense Raman bands near 143 and 994 cm^{-1} ⁶¹, its presence can be excluded in these samples. Infrared spectra provide additional complementary information. The infrared bands near 1580, 1456 and a shoulder near 1380 cm^{-1} present in the dehydrated samples are attributed to carbonaceous deposits. In particular, the band at 1580 cm^{-1} is characteristic of C=C bond stretching in polycyclic aromatic compounds, while the weaker bands near 1456 and 1380 cm^{-1} have been attributed to the bending modes of $-\text{CH}$, $-\text{CH}_2$ and $-\text{CH}_3$ species in carbonaceous deposits⁶³⁻⁶⁴. The presence of bidentate carbonates (weak features at about 1550, 1315 and 1060 cm^{-1})⁶⁵ cannot be excluded either. The sharp band near 2339 cm^{-1} is associated with occluded CO_2 ⁶⁶⁻⁶⁷ that could be retained in the material closed porosity. This CO_2 may originate from the calcination of the carbonaceous precursors.

2) Studying catalysts during reaction

The catalysts were all inactive below 200 °C; above this temperature, the conversion raises gradually. Table S1 shows the activity results obtained by MS and FTIR spectra from the gas phase during propane ODH experiments in the IRRaman reactor at 340 °C . These results are consistent with those obtained with the same samples in a conventional fixed bed microreactor ⁴⁸, which validates the catalytic relevance of the data obtained in the IRRaman reactor (i.e., it is a genuine *operando* reactor) and the temperature control.

These activity data were compared with the evolution of the Raman and FTIR *operando* spectra (Figure 4). In order to fully characterize the catalysts, spectra were acquired at 340 °C both in the presence and absence of oxygen, and with an activation flow before and after reaction. FTIR spectra in the 1750-1100 cm⁻¹ region provide information about the adsorbed oxygenated species (Figure 4-1). In the 1100-900 cm⁻¹ region, FTIR bands related to V=O bonds are detected (Figure 4-2) and can be directly compared to the Raman results presented in the region 1100-525 cm⁻¹ (Figure 4-3). Adsorbed species were removed by heat treatment in presence of O₂ before starting each experiment.

Figure 4. Operando FTIR (1 and 2) and Raman (3) spectra for (A) Zr-V2.5, (B) Zr-V5.0 and (C) Zr-V6.4 at 340°C. IR spectra shown at 1700-1100 cm⁻¹ (1) were all subtracted with the reference spectrum of the sample under activation flow at the same temperature. Green and yellow traces represent experiments using *ODH* and *DH* feeds, respectively. Spectra represented in green correlate with the activity results presented in Table S1. Blue and pink traces represent experiments using activation flow *before* and *after* reaction, respectively.

The catalysts exhibit some infrared bands in the region of adsorbed species during ODH reaction (green spectra in Figure 4-1). These bands correspond to a mixture of bidentate acetates (1540 , 1448 , and 1355 cm^{-1}), acrylates (~ 1640 , 1540 , 1440 , and 1355 cm^{-1}) and bidentate formates (1570 , 1371 , and 1350 cm^{-1})^{70–75}. Interestingly, bands in the same range are also observed at 200°C , but only for the highest vanadium loading (Figure S2). In these formates are predominant and they remain stable upon oxidation. Being this catalyst, as the others, inactive at 200°C , formate species are thus likely to have a moderate role in the reaction scheme. Conversely, at 340°C , the adsorbed species are almost completely removed upon reoxidation (Figure 4, pink spectra); the concomitant detection of CO_x and water in the gas phase suggests that these surface adsorbed species are intermediates of the total oxidation pathway. The proportion of acetates and acrylates with respect to that of formates increases with the vanadium content, especially in the most active catalyst (Zr-V6.4). This could indicate that acetates and acrylates preferentially adsorb on more polymerized vanadium species. A small shift and a slight intensity decrease of the infrared $\text{V}=\text{O}$ modes (Figure 4-2) is apparent during reaction (green spectra) with respect to the initial activated state (blue spectra), this effect being more noticeable as the vanadium content increases. These small perturbations observed during reaction disappear, as the adsorbed oxygenate species, upon reoxidation (pink spectra), and thus could somehow be associated to the interaction of the $\text{V}=\text{O}$ bond with the adsorbed species. The Raman spectra of all the catalysts (Figure 4-3) show a significant decrease in the intensity of the bands associated to $\text{V}-\text{O}-\text{V}$ and $\text{V}-\text{O}-\text{Zr}$ bonds during reaction (green spectra) with respect to the fresh catalyst (blue spectra). These bands are completely restored upon oxidation of the fresh activated

catalysts (blue spectra), suggesting that V-O-V and V-O-Zr species participate in the propane ODH reaction, being most probably the active sites. These results are in agreement with previous findings that determine a higher reactivity of the bridging oxygen (V-O-V and V-O-Support) with respect to the terminal oxygen of the vanadyl group ⁷⁷.

In additional reaction experiments without O₂ (DH; yellow spectra), the FTIR spectra of Figure 4-1 show more adsorbed oxygenates -especially acetates- than in ODH conditions. As reported in the literature ⁷⁶, lattice oxygen is not involved in formates conversion to CO. Conversely, the development of acetates and acrylates implies catalyst reduction (i.e., consumption of lattice oxygen). Therefore, during DH, acetates dominate because only the formates are removed. During ODH, both acetate and formate species are formed and removed, giving rise to a steady state structure characterised by a spectrum which is just a mere linear combination of both IR spectra. These differences are not observed between the DH and ODH spectra for the catalysts with higher vanadium content (Zr-V5.0 and Zr-V6.4), since they already present a higher proportion of acetates with respect to formates.

During DH, carbonaceous deposits form, as evidenced by a shoulder around 1600 cm⁻¹ in the FTIR spectra and Raman bands of carbon compounds around 1430 and 1600 cm⁻¹ (Supporting Information, Figure S3). Moreover, the V=O mode remains mildly affected in the FTIR spectra (Figure 4-2), although there is a complete depletion of the V=O and polyvanadate Raman bands (Figure 4-3).

An interesting aspect is that when the Raman signal is lost the infrared spectra show a split of the vanadyl band in two (or more) modes and these facts must be

related. We cannot determine the configuration of the supported oxide, but either the symmetry or electronic state of vanadia result in a silent Raman signal or for some reason Raman signal is lost under these conditions whatever the vanadia loading. Further studies with simultaneous IR and Raman reading shall enable understanding what configuration is generated.

The evolution of reaction products during DH monitored by IR spectroscopy for Zr-V6.4 at 340°C is shown in the Supporting Information, Figure S4. The initial products are propylene, CO and CO₂, and their concentration decreases with time as the lattice oxygen of the catalysts is being exhausted. The fact that these oxygenated products are detected during some minutes confirms the participation of lattice oxygen in the reaction, in line with a Mars-Van Krevelen type mechanism. This is confirmed by the major decrease of the V-O-V/V-O-Zr bands, which suggests the contribution of these bridging oxygen atoms to the oxidation. When oxygen is fed again, both the activity and the V-O-V/V-O-Zr bands are recovered, demonstrating the reversibility of the redox behavior of these catalysts. The absence of changes when inert flow is fed after reaction instead of oxygen demonstrates that the catalyst reoxidation (or the recovery of the vanadia bands to the initial state) and the removal of the adsorbed species (mainly acetates and carbonaceous deposits) are only possible if there is oxygen in the gas phase.

In summary, while the *operando* approach is required to provide the necessary catalytic data to establish structure activity relationships, the simultaneous acquisition of IR and Raman spectra allows an extensive evaluation of the adsorbed species and their impact on the working catalyst.

Conclusions

A new multimodal *operando* reactor-cell was developed for simultaneous Raman and transmission FTIR *operando* spectroscopies ("IRRaman" reactor) and validated with V-Zr-O catalysts during propane ODH reaction. The combination of complementary spectroscopies allows both the identification of the reaction intermediates (oxygenated species detected by FTIR) and obtaining complete structural information (evolution of V=O and V-O-V/V-O-Zr bonds on the catalysts followed by FTIR and Raman). The V=O mode, detected in Raman and infrared, has the same frequency in both spectra, since they are measured under identical conditions. The V-O-V/V-O-Zr oxygen sites were found to be more active than those in the terminal V=O bond, shedding additional light on the role of the different oxygen species in the reported Mars-van Krevelen mechanism for zirconia-supported vanadia.

As an outlook, the new *operando* multimodal device can provide fundamental insight into many reaction mechanisms thanks to its capacity to associate concomitant information from surface adsorbed species and catalyst structure evolution under stream in a single rig, on the same sample, at the same time and under relevant operating conditions. This device could also find useful applications in the study of materials in evolution under heat and/or under controlled atmosphere.

- Figure S3. *Operando* Raman spectra for Zr-V2.5, Zr-V5.0 and Zr-V6.4 in the 1300-1600 cm⁻¹ region during DH reaction (20% propane in He) at 300 and 340°C.
- Figure S4. Evolution of the gas phase with time. FTIR spectra of Zr-V6.4 catalyst during DH reaction (20% C₃H₈ in Ar) at 340°C.

1. Catalyst synthesis

Zirconium (IV) propoxide solution (Sigma-Aldrich, CAS: 23519-77-9, 70 wt. % in 1-propanol), polyvinylpyrrolidone (PVP) (Sigma-Aldrich, CAS: 9003-39-8, Mw ~1,300,000), acetylacetone (Sigma-Aldrich, CAS: 123-54-6, ≥99%), 1-propanol (Sigma-Aldrich, CAS: 71-23-8, ≥99.5%) and vanadyl acetylacetonate (Sigma-Aldrich, CAS: 3153-26-2, ≥97.0%) were used as starting materials. The catalysts were prepared by electrospinning. The synthesis of the solutions has previously been describedⁱ. Briefly, the starting polymer solution was prepared by dissolving 2.100 g of the zirconium fibers precursor (zirconium (IV) propoxide) and 0.317 g of PVP in 2.984 g of 1-propanol solvent with 0.450 g of acetylacetone. Then, vanadyl acetylacetonate was added to three fractions of this polymer solution to obtain final fibers with nominal vanadium mass concentrations of 2.5% (Zr-V2.5), 5.0% (Zr-V5.0) and 6.4% (Zr-V6.4). Subsequently, the three polymer solutions were vigorously stirred for 24 h at room temperature. The electrospinning equipment and procedure have also been described in previous articles^{i,ii}. The electrospun fibers were calcined in air flow (150 mL·min⁻¹ STP) at 500 °C in a conventional tubular furnace, with a heating rate of 10 °C·min⁻¹ followed by 6 h dwell time in order to eliminate the organic part and the remaining solvent, and to stabilize the zirconia fibers. The final vanadium mass concentration obtained by XPS analysis of Zr-V2.5, Zr-V5.0 and Zr-V6.4 samples was reported to be 2.7, 4.9 and 6.0%, respectively^{i,ii}.

2. The “IRRaman” reactor

The IR-Raman *operando* rig was adapted from a home-made *operando* IR reactor-cell (the so-called “Sandwich” reactor)ⁱⁱⁱ. The cell was notably modified by replacing the two KBr windows positioned on one side of the cell by a stainless steel cylinder. Two holes were drilled in the cylinder, one to accommodate the Raman probe and another one for a dedicated small KBr window (d=4 mm) to let the IR beam pass through. Air tightness was guaranteed via Kalrez O-rings. The position of the Raman probe, and thus the distance to the pellet surface (approximately 1 mm), is adjustable to optimize the signal intensity. The pellet temperature is measured via a calibrated thermocouple placed on the sample holder to ensure proper temperature control independently of the new reactor configuration and construction materials.

3. ODH reaction conditions

Three catalytic materials (Zr-V2.5, Zr-V5.0 and Zr-V6.4) were pressed into self-supported wafers and tested for ODH in the IRRaman *operando* reactor. The weight of catalyst (W_{cat}) and the total volumetric gas flow (F_T) were 31.5 mg and 18.1 mL·min⁻¹, respectively, resulting in a space-time ($W_{\text{cat}}/F_{\text{C}_3\text{H}_8}$) of 0.53 g_{cat}·s·mL⁻¹_{C₃H₈}. The reaction temperature was varied from 200 to 340°C. Two different gas mixtures were used in the ODH experiments, an activation flow of 10% oxygen in argon, and a reaction flow consisting of a mixture of 20% propane and 10% oxygen in argon. Dehydrogenation (DH) experiments were also carried out without oxygen in the activation and reaction flows. Gas lines were heated at 60°C before and after the reaction-cell to pre-heat the reaction mixture and to avoid products condensation.

The samples were first dehydrated by heat treatment under activation flow from room temperature to 340°C with a heating rate of 5°C·min⁻¹. After dehydration and equilibration at the selected reaction temperature, the samples were submitted to activation and reaction flows with and without oxygen in different order. The conditions were changed when the steady state was achieved.

Operando FTIR and *operando* Raman spectra of the catalysts were acquired every 2 and 4 min, respectively. Reactants and products of the gas phase were analyzed online by FTIR gas cell (one spectrum every 2 min), and mass spectrometry (one measurement every 3 s). Under reaction flow the carbon molar balances were always attained with a maximum error of 5%. Propane or oxygen conversion ($X_{C_3H_8}$ or X_{O_2} , respectively) and the selectivity to product “i” (S_i) were calculated as follows:

$$X_i(\%) = \frac{\dot{F}_{o,i} - \dot{F}_i}{\dot{F}_{o,i}} 100 \quad (\text{Eq. S1})$$

$$S_i(\%) = \frac{n_i \dot{F}_i}{n_{C_3H_8} \dot{F}_{0,C_3H_8} X_{C_3H_8}} 100 \quad (\text{Eq. S2})$$

where $\dot{F}_{o,i}$ and $\dot{F}_i$ are the molar flows of “i” reactant/product in the inlet and in the outlet streams, respectively, and n_i is the number of carbon atoms per molecule of “i” compound ($n_{C_3H_8} = 3$).

Turn-over frequency (TOF) was calculated from Eq. S3; it quantifies the specific activity under defined reaction conditions per vanadium atom describing the number of converted moles of propane per mol of vanadium and time:

$$\text{TOF} = \frac{\dot{F}_{0,C_3H_8} X_{C_3H_8} M_V}{W_{\text{cat}} W_V} \quad (\text{Eq. S3})$$

where M_V is the molar mass of vanadium and W_V the mass of vanadium per gram of catalyst.

The TOF values are calculated assuming that all vanadium atoms are exposed on the catalysts, hypothesis supported by the absence of crystalline vanadia observed by Raman and by the fact that the nominal vanadia loading and the surface vanadia concentration calculated from XPS data are very similar.

Blank experiments were performed under reaction flow without catalyst and with a vanadium-free zirconia sample, in order to discard a possible contribution of the homogeneous phase reaction and/or of the zirconia support to the propane ODH catalytic results at the temperatures studied. In both cases propane conversion values were negligible.

4. Catalytic and spectroscopic results.

Table S1. Activity results obtained during the operando experiments in the IRRaman reactor at 340°C (Catalyst weight: 31.5 mg, total flow: 18,1 mL·min⁻¹, space-time: 0.53 g·s·mL_{C₃H₈}⁻¹). Results are reported in steady state where no significant deactivation was observed.

Sample	X _{C₃H₈} (%)	X _{O₂} (%)	S _{C₃H₆} (%)	S _{CO_x} (%)	Y _{C₃H₆} (%)	TOF ^a (10 ⁻³ ·s ⁻¹)
Zr-V2.5	1.3	6.6	71.4	28.6	0.93	2.02
Zr-V5.0	3.2	10.9	75.8	24.2	2.42	2.74
Zr-V6.4	5.3	24.3	58.5	41.5	3.10	3.71

^a TOF based on XPS analyses.

Table S2. XPS results previously obtained for catalyst compositionsⁱ, used to calculate the TOF values.

Sample	XPS (wt %)			
	V2p	Zr3d	O1s	C1s
Zr-V2.5	2.7	66.1	24.2	7.0
Zr-V5.0	4.9	64.3	27.9	2.9
Zr-V6.4	6.0	59.8	24.8	9.4

Figure S1. XRD patterns of the catalysts (Zr-V2.5, Zr-V5.0 and Zr-V6.4). Tetragonal (T) ZrO₂ (JCPDS 01-079-1769) is found in all the diffractograms.

Figure S2. Operando FTIR (1 and 2) and Raman (3) spectra for (A) Zr-V2.5, (B) Zr-V5.0 and (C) Zr-V6.4 at 200°C. IR spectra shown at 1700-1100 cm^{-1} (1) were all subtracted with the reference spectrum of the sample under activation flow at the same temperature. Green traces represent experiments using ODH. Blue and pink traces represent experiments using activation flow before and after reaction, respectively.

Figure S3. Operando Raman spectra for Zr-V2.5, Zr-V5.0 and Zr-V6.4 in the 1300-1600 cm⁻¹ region during DH reaction (20% propane in He) at 300 and 340°C.

Figure S4. Evolution of the gas phase with time. FTIR spectra of Zr-V6.4 catalyst during DH reaction (20% C₃H₈ in Ar) at 340°C.
