ABSTRACT

Dairy whey was hydrolyzed for 15 min with five food-grade enzymes (Alcalase, Neutrase, Corolase 7089, Corolase PN-L, and Papain) at atmospheric pressure (0.1 MPa) and in combination with high pressure (HP) at 100, 200, and 300 MPa, applied prior to or during enzymatic digestion. The peptide profile of the hydrolysates obtained was analyzed by sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE), and their residual antigenicity was assessed by immunoblotting with anti- β -lactoglobulin monoclonal antibodies and the sera from pediatric patients allergic to cow's milk proteins. Moreover, to evaluate the presence of residual trace amounts of casein in bovine whey hydrolysates, immunoblotting with anti-cow's milk protein polyclonal antibodies was performed. SDS-PAGE analysis showed that HP treatment increased hydrolysis by the proteases assayed, especially when it was applied during the enzymatic digestion. Positive reactions at the band corresponding to β -lactoglobulin were detected for Corolase PN-L and Corolase 7089 hydrolysates, except for those obtained under 300 MPa by the last protease. However, the immunochemical reaction was lower in the hydrolysis products obtained under HP than in those obtained at atmospheric pressure and after the HP treatment. On the contrary, no residual immunochemical reactivity associated with β -lactoglobulin was observed in the hydrolysates obtained by Alcalase and Neutrase under HP, and none was observed in any of the hydrolysis products obtained by Papain. The presence of traces of casein was not significant. These results suggest that HP combined with selected food-grade proteases is a treatment that can remove the antigenicity of whey protein hydrolysates for their use as ingredients of hypoallergenic infant formulae.

Breast feeding is the most suitable form of nutrition for neonates because of the specific nutrients as well as the growth and defense factors contained in human milk (16). When breast feeding is not possible, children are generally fed cow's milk formulae, which can induce immunological responses in some allergic subjects. This syndrome is known as cow's milk allergy, and its prevalence ranges from 0.5 to 7.5% in infants who are fed formulae containing cow's milk proteins (10). For this reason, hypoallergenic formulae based on protein hydrolysates have been developed, to reduce the antigenicity of milk proteins. However, several reports have described residual immuno-reactivity, even in these preparations (5, 21, 24–26, 30).

Over the last decade, high pressure (HP) has been described as an excellent nonthermal technique for food preservation (19), because the microbial population can be decreased without modification of the sensorial and nutritional properties (22, 23). HP is a valuable tool also in the production of hypoallergenic protein hydrolysates, as shown by several scientific articles in which the enhancement of enzymatic proteolysis of bovine β -lactoglobulin by different proteases in combination with HP has been described

(3, 6, 7, 13, 18, 31). A selective hydrolysis by thermolysin in whey protein concentrates under 200 MPa was found by Hayashi et al. (9), and an increase of the proteolytic digestion of soybean whey proteins by pepsin, trypsin, and chymotrypsin combined with HP, applied prior to or during the hydrolysis, was shown previously by our group (19).

Nakamura et al. (14) described a reduction of the antigenicity of whey protein hydrolysates obtained by Papain and proleather enzymes after pressurization up to 400 MPa, and an absence of immunochemical reactivity in the peptides obtained after the hydrolysis of β -lactoglobulin by chymotrypsin under HP has been reported by Bonomi et al. (3).

However, to our knowledge, there is no information in the literature about the effect of the combination of HP and enzymatic proteolysis of cow's milk by food-grade proteases on the immunochemical reactivity of the protein hydrolysates.

The purpose of this study was to assess the residual antigenicity of the hydrolysis products obtained in the proteolytic digestion of bovine whey by food-grade enzymes in combination with HP, applied prior to or during the hydrolysis, with the aim of producing hydrolysates suitable for hypoallergenic infant formulae.

MATERIALS AND METHODS

Sample preparation. Bovine whey was obtained from pasteurized skimmed bovine milk purchased in a Spanish supermarket and was converted to whey by acidification at pH 4.6 with 4 N lactic acid. Then, the milk was centrifuged at $8,000 \times g$ for 15 min to remove the residual casein curd. The supernatant obtained was the whey, which was freeze dried and then dissolved in distilled water at a concentration of 5% (wt/vol). HP used the whey solution (WP) as a substrate of the enzymatic hydrolysis performed after or during its treatment. The untreated WP was also hydrolyzed.

The pH of the WP was adjusted with 1 N sodium hydroxide (PRS grade, 98 to 100%; Panreac, Barcelona, Spain) prior to its hydrolysis. The pH of the solution was 6 for the hydrolysis with Corolase PN-L (EC 3.4.21.63; AB Enzymes, Darmstadt, Germany) and 7 for the hydrolysis with Alcalase (EC 3.4.21.62; Novozymes, Bagsvaerd, Denmark), Neutrase (EC 3.4.24.28; Novozymes), Corolase 7089 (EC 1.5.1.15; AB Enzymes), and Papain (EC 3.4.22.2; Fluka, Buchs, Switzerland).

HP treatment. HP treatments were performed in a discontinuous HP machine (ACB GEC, Alsthom, Nantes, France) with a hydrostatic pump and a steel vessel of 2.35-liter capacity (100 mm in diameter and 300 mm in height). The vessel was filled with water as a fluid of low compressibility. During the treatment, the temperature was held constant by an external circulating thermostatic bath. In each experiment, the target pressure was achieved within 1 to 2 min, held for 15 min, and then released to atmospheric pressure within 1 to 2 min. The treatments were repeated three times on individual samples.

The WP and the hydrolysis reactions, 15 ml in all cases, were subjected to three different pressure treatments (100, 200, and 300 MPa) for 15 min at different temperatures (40, 50, or 70°C) depending on the protease used in the enzymatic reaction.

Proteolytic procedure. Three sets of experiments of proteolysis were separately performed with the following five enzymes: Alcalase, Neutrase, Corolase 7089, Corolase PN-L 100, and Papain. Alcalase is an endopeptidase from *Bacillus licheniformis* that cleaves the peptide bonds of protein near serine, glycine, and aromatic amino acids into large peptides; Neutrase is a metalloendopeptidase from *Bacillus amyloliquefaciens* that preferentially cleaves bonds involving hydrophobic amino acids; Corolase 7089 is an endoproteinase from *Bacillus subtilis*; Corolase PN-L is an endoproteinase and exopeptidase from *Aspergillus sojae*; and Papain is a proteinase from *Carica papaya* with a broad specificity for peptide bonds and a preference for cleavage of a residue bearing a large hydrophobic side chain at the P2 position.

In the first set of experiments, the hydrolysates (HA) were produced at atmospheric pressure (0.1 MPa) with untreated WP. These samples were considered the control of the experiments. An amount of 15 ml of WP (5%, wt/vol) and a 1:20 (vol/wt) enzyme-to-substrate ratio (E:S) were used for the liquid enzymes (Alcalase, Neutrase, Corolase 7089, and Corolase PN-L) in the hydrolysis reactions. For Papain, the E:S ratio was 1:20 (wt/wt). Hydrolysis was carried out at 40°C for the reaction with Corolase PN-L, at 50°C for the reactions with Alcalase, Neutrase, and Corolase 7089, and at 70°C for the reaction with Papain.

In the second set of experiments, the WP was packed into polyethylene bags and pressurized for 15 min prior to the enzymatic digestion (P100 to P300). The temperatures of the treatment were 40 and 70°C for the WP destined to be used for the hydrolysis with Corolase PN-L and Papain, respectively, and 50°C for use with Alcalase, Neutrase, and Corolase 7089. After the release

of pressure, the treated WP was hydrolyzed at atmospheric pressure (0.1 MPa) for 15 min, as described above.

In the third set of proteolytic experiments, the WP was digested (HP, 100 to 300) under HP by the five proteases separately with the substrate concentration and E:S ratio as described above. The protease was added to the WP, and each mixture was distributed into polyethylene bags separately and maintained at 0°C until its incubation under pressure.

Incubations without enzymes were performed in the three sets of experiments; the hydrolysis was carried out in triplicate, stopped by heating for 5 min at 90°C, and stored at -20°C until analysis.

Allergic children. Sera used in this study were from 2 of 29 atopic children who arrived in 2004 at the emergency unit of Macedonio Melloni Hospital with acute allergic symptoms after ingestion of cow's milk formula. The two subjects presented the following clinical characteristics. Subject 1 was a male, aged 3.56 years, whose skin prick test yielded the following values: α -lactalbumin, 15 mm; casein, 6 mm; and β -lactoglobulin, 8 mm (positive responses, ≥ 3 mm). His CAP test (Pharmacia & Upjohn Diagnostics, Uppsala, Sweden) yielded the following values: α -lactalbumin, 3.09 kU/liter; casein, 1.82 kU/liter; and β -lactoglobulin, <0.35 kU/liter (positive responses, >0.35 kU/liter). Subject 2 was a female, aged 0.9 year, whose skin prick test yielded the following values: α -lactalbumin, 6 mm; casein, 10 mm; and β -lactoglobulin, 12 mm. Her CAP test (Pharmacia & Upjohn) yielded the following values: α -lactalbumin, 10.6 kU/liter; casein, 19.3 kU/liter; and β -lactoglobulin, 2.71 kU/liter.

They were not given an oral challenge because of the high risk of anaphylaxis. Informed consent was obtained from the parents of all children included in the study. Some control sera (healthy subjects) were tested for their reactivity to cow's milk proteins.

SDS-PAGE. The electrophoretic analysis of bovine whey hydrolysates was performed by nonreducing sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) with a gradient running gel of 12 to 22% polyacrylamide, prepared according to Restani et al. (26), omitting 2-mercaptoethanol from the denaturing buffer. The gradient running gel was made up of 9 to 19% acrylamide; 0.08 to 0.17% bisacrylamide; 0.36 M Tris-HCl buffer, pH 8.8; 35% glycerol; 0.1% SDS; 0.02% ammonium persulfate; and 0.15% *N,N,N',N'*-tetramethylethylenediamine. The stacking gel was made up of 3.5% acrylamide; 0.09% bisacrylamide; 0.125 M Tris-HCl buffer, pH 6.8; 0.1% SDS; 0.02% ammonium persulfate; and 0.15% *N,N,N',N'*-tetramethylethylenediamine. The running buffer was made up of 25 mM Tris, 0.19 M glycine, and 0.1% SDS (wt/vol), pH 8.8.

After the electrophoretic run (90 V at room temperature, for approximately 6 h), gels were dyed with Coomassie brilliant blue G-250 by the method of Neuhoff et al. (15). All materials and instruments were purchased from Bio-Rad (Richmond, Calif.).

The molecular weights of the polypeptidic fragments obtained after the hydrolysis were determined with a broad-range molecular weight standard marker solution purchased from Bio-Rad. It contained the following: rabbit skeletal myosin muscle (200 kDa); *Escherichia coli* β -galactosidase (116.25 kDa); rabbit muscle phosphorylase *b* (97.4 kDa); bovine serum albumin (66.2 kDa); chicken egg ovalbumin (45 kDa); bovine carbonic anhydrase (31 kDa); soybean trypsin inhibitor (21.5); chicken egg lysozyme (14.4 kDa); and bovine pancreas aprotinin (6.5 kDa).

Immunoblotting. After SDS-PAGE, proteins were transferred to a polyvinylidene difluoride membrane (Millipore Corp.,

Bedford, Mass.) by Western blotting in a Trans-blot Electrophoretic Transfer Cell (Bio-Rad).

The membranes were blocked with 1% gelatin and washed three times with 0.25% gelatin solution (in 150 mM NaCl, 5 mM EDTA, 50 mM Tris, and 0.05% Triton X-100) to prevent nonspecific adsorption of the immunological reagents. The membrane was then immersed in 10 ml of 0.25% gelatin solution containing 0.3 ml of sera from children allergic to cow's milk proteins or 10 μ l of murine anti- β -lactoglobulin monoclonal antibodies (produced by ourselves). Since residual trace amounts of casein frequently remain in whey preparations, immunoblottings were also performed by anti-cow's milk protein polyclonal antibodies (produced by us) that recognized both whey proteins and caseins.

Secondary antibodies labeled with alkaline phosphatase detected antigen-antibody complexes. Specifically, goat anti-human immunoglobulin E antibodies (Sigma-Aldrich, St. Louis, Mo.) were for human sera, goat anti-mouse immunoglobulin G antibodies (Sigma-Aldrich) were for monoclonal antibodies, and monoclonal anti-rabbit immunoglobulin G antibodies were for polyclonal antibodies.

The secondary antibodies (commercial stock) were diluted 1:1,000 (vol/vol) in 0.25% gelatin solution. After incubation for 4 h at room temperature with agitation, the membranes were washed twice with 0.25% gelatin solution (2 min each) and once with Tris Buffer Solution (20 mM Tris and 0.5 NaCl) for 2 min.

Finally, after incubation in 5-bromo-4-chloro-3-indolylphosphate toluidinium-nitroblue tetrazolium (Merck, Darmstadt, Germany) solution, an intense black-purple precipitate developed at the site of enzyme binding. The developing solution contained 15% 5-bromo-4-chloro-3-indolylphosphate toluidinium and 30% nitroblue tetrazolium in alkaline phosphatase buffer (100 mM Tris, 100 mM NaCl, and 5 mM $MgCl_2$, pH 9.5).

Image analysis. Image analysis of membranes was performed by a gel scanner (Sharp JX-330, Pharmacia Biotech, Uppsala, Sweden) and Image Master 1D Software.

RESULTS AND DISCUSSION

Immunoblotting with monoclonal and polyclonal antibodies and the sera of allergic patients was used to check the effect of HP on immunochemical properties of dairy whey (WP) hydrolysates obtained by five food-grade enzymes. The electrophoretic separation of the hydrolysis products showed that the application of HP prior to or during enzymatic digestion enhanced the extent of proteolysis compared with the control and also affected the aggregation-polymerization patterns (data not shown). Papain produced the highest levels of hydrolysis at all tested conditions when compared with the other enzymes. No protein or aggregate bands were observed in Papain digestion of untreated and pressurized WP proteins, before or during their enzymatic treatments. All hydrolysates showed bands with an apparent molecular mass that was <14.4 kDa.

Our findings on the increase of the extent of hydrolysis when the digestion was performed in combination with HP treatment are in consensus with the results reported by several authors for dairy and soy proteins (13, 19, 29, 31). The structure of the proteins at the secondary, tertiary, and quaternary levels could be affected by pressure (12) leading to protein denaturation (1, 2, 11, 28), a phenomenon that may favor their attack by proteolytic enzymes, enhancing the proteolysis.

Evaluation of the presence of β -lactoglobulin in bovine whey hydrolysates. Since β -lactoglobulin is the main allergen among cow's milk whey proteins (17), the presence of residues of this protein in different hydrolysates was evaluated with monoclonal anti- β -lactoglobulin antibodies. The results obtained with Alcalase are shown in Figure 1a. Antibodies recognized protein bands at the R_f of β -lactoglobulin in the unhydrolyzed bovine whey (HU). Also, a positive reaction was observed for hydrolysates obtained at atmospheric pressure (HA) and when HP treatment at 100 and 200 MPa was applied before the proteolysis (P100 and P200). However, a complete lack of immunoreactivity was found in products obtained under HP (HP100, HP200, and HP300) and with prepressurization at 300 MPa (P300).

The same pattern was detected for all peptides resulting from the proteolytic attack by Neutrase (Fig. 1b), where the antigenic responses specific for β -lactoglobulin were associated with the control hydrolysates (HA) and those obtained after the HP treatment (P100, P200, and P300). A lower antigenic response was found for samples hydrolyzed under HP (HP100, HP200, and HP300), and positive reactions were mainly associated with polymeric forms of β -lactoglobulin.

These results suggest that the application of HP during the enzymatic digestion by Alcalase and Neutrase was able to improve the hydrolysis of the antigenic determinants of β -lactoglobulin. On the other hand, positive responses associated with β -lactoglobulin were observed in all patterns from Corolase 7089 proteolysis (Fig. 1c), with the exception of the hydrolysis product obtained at 300 MPa (HP300), which showed no positive response. Samples hydrolyzed at 100 and 200 MPa (HP100 and HP200) showed lower immunochemical reactivity when compared with those pretreated by HP (P100 and P200), and these samples also showed a positive response to polymeric forms of β -lactoglobulin. These findings confirmed once more that the highest reduction of the antigenicity occurred when pressure was applied during the enzymatic hydrolysis.

A positive reaction associated with β -lactoglobulin was found for hydrolysis products obtained by Corolase PN-L (Fig. 1d), although the antigenic response was lower in hydrolysates obtained under and after pressurization at 300 MPa (lanes HP300 and P300, respectively).

Negative responses were obtained in all Papain hydrolysates (Fig. 1e), confirming the extensive hydrolysis of whey proteins by this enzyme observed in the electrophoretic analyses.

Our findings suggest that HP combined with enzymatic hydrolysis reduced the antigenic response of the hydrolysates when compared with the results of hydrolysis at atmospheric pressure. Several authors have reported on the denaturation of proteins under HP at specific cleavage sites that favor the accessibility of the proteases to the proteins (3, 4, 9, 13, 19, 29), which could lead to the elimination of their antigenic determinants. Our results show that the pressure treatment applied during the enzymatic digestion was more effective on the reduction of the immunoreactivity than when it was applied before the proteolysis. This phenomenon could be related to the structural unfolding and

FIGURE 1. Immunoblotting of polypeptides obtained by hydrolysis of bovine whey proteins with Alcalase (a), Neutrase (b), Corolase 7089 (c), Corolase PN-L (d), and Papain (e) incubated with monoclonal anti- β -lactoglobulin antibodies. MK, molecular weight standard solution; HU, unhydrolyzed bovine whey; HA, hydrolysis at atmospheric pressure (0.1 MPa); P100, hydrolysis after pressurization at 100 MPa; P200, hydrolysis after pressurization at 200 MPa; P300, hydrolysis after pressurization at 300 MPa; HP100, hydrolysis at 100 MPa; HP200, hydrolysis at 200 MPa; HP300, hydrolysis at 300 MPa.

denaturation of WP proteins induced by HP (8, 27) in the moment that the enzymes were present, which could favor the exposure of conformational antigenic epitopes to proteases.

Evaluation of the presence of bovine caseins in bovine whey hydrolysates. To evaluate the possible presence of bovine casein traces in bovine whey hydrolysates, polyclonal antibodies produced against all cow's milk proteins were used. The results obtained are shown in Figure 2.

In spite of their low specificity against β -lactoglobulin, these polyclonal antibodies confirmed the data shown in Figure 1 and, moreover, allowed us to conclude that the presence of a significant quantity of casein was excluded in the Alcalase, Corolase 7089, and Papain hydrolysates obtained at atmospheric pressure (control) and by HP applied prior to or during the enzymatic digestion (Fig. 2a, c, and d). By contrast, a positive reaction associated with casein was found for the hydrolysis products obtained by Neutrase and HP, although the antigenic response was lower in hydrolysates obtained at or after pressurization at 200 and 300 MPa (Fig. 2b) and by Corolase PN-L when WP was subjected to pressurization before enzymatic digestion (Fig. 2d, lanes P100, P200, and P300). Negative responses were, however, observed in Corolase PN-L hydrolysates performed at 100, 200, and 300 MPa (Fig. 2d, lanes HP100, HP200, and HP300).

Immunoblotting with sera of children allergic to cow's milk. To verify the immunoreactivity of the hydrolysates assayed in this research, immunoblottings with sera from two children allergic to whey proteins were performed.

Since the data obtained for the incubation of the membranes with the two sera were similar, only the results from one child are shown in Figure 3. The results obtained with human sera are very similar to those obtained with the polyclonal antibodies (Fig. 2) developed against all cow's milk proteins and confirm previous reports on the reduction of the protein antigenicity by combining HP treatment and enzymatic proteolysis (3, 14, 17, 20). Besides, these findings are in agreement with the results obtained by our group on the decrease of immunoreactivity of soybean whey proteins (19) and bovine whey proteins hydrolyzed by trypsin and pepsin in combination with pressure treatment (18).

The results of the present study suggest that the combination of high hydrostatic pressure and enzymatic proteolysis with selected food-grade proteases can decrease or remove the immunochemical reactivity of whey protein hydrolysates and that these methods can be applied in the production of hypoallergenic infant formulae. Further studies are now in progress to optimize the pressure-enzymatic treatments in order to remove completely the antigenicity of whey protein hydrolysates. Moreover, other *in vitro* and *in vivo* tests will be performed to confirm the results ob-
