†Our friend and colleague Alain Bouquet, who actively participated in this work and co-authored this manuscript, passed away unexpectedly during its final writing. He enjoyed a very productive scientific life, dedicated to the biology of grapevine and its genetic improvement, and he was an enthusiastic and wonderful person, professor and colleague. We dedicate this article to his memory.

SUMMARY

We have characterized the genetic and molecular origin of the reiterated reproductive meristem (RRM) somatic variant phenotype of grapevine cultivar Carignan. Here, we show that the extreme cluster proliferation and delayed anthesis observed in this somatic variant is caused by a single dominant mutation. Transcriptional profiling of Carignan and RRM plants during early stages of inflorescence development demonstrated the overexpression of a few regulatory genes, including *VvTFL1A*, a close *TFL1* Arabidopsis homolog, in RRM inflorescences. Genetic and molecular analyses correlated the insertion of a class-II transposable element, *Hatvine1-rrm*, in the *VvTFL1A* promoter, with upregulation of the corresponding *VvTFL1A* allele in reproductive and vegetative organs of the shoot apex. These results suggest a role for this *TFL1* grapevine homolog in the determination of inflorescence structure, with a critical effect on the size and branching pattern of grapevine fruit clusters. Our results demonstrate the existence of spontaneous *cis*-activation processes caused by class-II transposable elements in grapevine plants, and point to their possible role as a mechanism to generate somatic cell variation in perennial plants. This mechanism is expected to generate dominant phenotypes in chimeric sectors that can be readily exposed to natural selection.

Keywords: inflorescence development, inflorescence structure, somatic variation, active transposition, grapevine.

INTRODUCTION

Fruit and forest trees are perennial plant species with long generation times, which has influenced their domestication, mostly by the selection and vegetative propagation of elite genotypes (Zohary, 2004). Long generation times facilitate the accumulation of genetic variation, affecting somatic cells that, given the lack of germ line-characterizing plants, can be transmitted to the next sexual generation (Walbot and Evans, 2003). Only a small proportion of the spontaneous somatic variation is phenotypically expressed within the sporophytic generation, given that mutant somatic cells are frequently heterozygous for recessive mutations, and present as chimeric sectors within the plant. Therefore, only gain-of-function mutations or loss-of-function mutations

causing haploinsufficiency will generate a phenotype under these conditions.

Somatic variation is important for genetic improvement in fruit trees, such as Citrus species (Moore, 2001) or grapes (This *et al.*, 2006), where vegetative reproduction is used to propagate new interesting phenotypes, appearing as spontaneous sports. In spite of its relevance, little is known about the genetic and epigenetic mechanisms causing this variation. From the time of grapevine (*Vitis vinifera*) domestication, dated to approximately 8000 years ago (McGovern *et al.*, 1986), the selection of elite genotypes and their vegetative propagation has been a common approach for cultivar improvement and management (Zohary and Hopf,

2000). Throughout grapevine domestication multiple spontaneous somatic variants have been selected in different cultivars for physiological and berry traits, such as earliness, cluster and berry size, seedlessness, berry taste, berry colour, etc. (This *et al.*, 2006). However, the molecular basis of this phenotypic variation is only known for two traits. On one hand, the cultivar Pinot Meunier, displaying tomentose vegetative organs when compared with its original cultivar, Pinot Noir, was shown to be a periclinal chimera carrying a gain-of-function mutation in *VvGAI1* in the L1 cell layer, which impairs gibberelic acid signaling (Boss and Thomas, 2002). On the other hand, red color berry variants, quite frequent in white berry cultivars, have been shown to appear as a result of recombination between long terminal repeats (LTRs) of the *Gret1* retrotransposon, present in the homozygous state at the promoter of *MybA1* in white cultivars (Kobayashi *et al.*, 2004; Lijavetzky *et al.*, 2006).

Grapevine somatic variants can also be useful tools for the study of gene function, because they result from the effect of single mutation events in a given genetic background. In this way, characterization of the *fleshless* somatic variant in cultivar Ugni Blanc has provided new tools to study ovary and fruit morphogenesis (Fernandez *et al.*, 2006, 2007). In addition, other somatic variants altered in reproductive development have been described, showing the possibilities of this type of natural variation in the study of woody plant development (Chatelet *et al.*, 2007). Among those variants, the reiterated reproductive meristems (RRM) somatic variant of cultivar Carignan exhibits an early phenotypic alteration of inflorescence development, and a delayed anthesis that affects fruit cluster development and ripening time (Chatelet *et al.*, 2007). Fruit cluster size and compactness as well as anthesis time and berry ripening are all traits of interest in grape production, either for wine making or direct fruit consumption.

Here, we have investigated the genetic and molecular origin of the RRM phenotype to shed light on the process of grapevine inflorescence and fruit cluster development, and to understand the molecular mechanisms responsible for this spontaneous phenotypic variation. Using a combination of genetic, transcriptomic and molecular approaches, we show that reiteration of reproductive meristems results from a spontaneous *cis*-activation of *VvTFL1A*, the grapevine homolog of *Arabidopsis TFL1*, suggesting a critical role of *VvTFL1A* in the proliferation and branching of inflorescences and tendril meristems in grapevine. Furthermore, we show that this *cis*-activation is caused by a new insertion of a class-II transposon in its promoter region, which seems to enhance its expression. Spontaneous 'activation tagging' mediated by endogenous transposons could represent a genetic mechanism to generate somatic variation that can be readily exposed to natural selection during the life of perennial species, contributing to their adaptation and evolution.

RESULTS

Morphological characterization of the RRM somatic variant

Reproductive development. The most conspicuous phenotype of the RRM somatic variant was the production of larger inflorescences, as well as a 1-month delay in the time of anthesis, with respect to the original Carignan plant (Figure 1a,b). This delay did not result from late flowering induction, as the analysis of shoot development showed that RRM plants developed the first inflorescence at an equivalent node position as Carignan, and produced a similar number of inflorescences per shoot (data not shown).

The RRM inflorescences also produced a higher number of flowers per floral group than Carignan plants. These flower groups developed asynchronously, showing a gradient, from flower meristem to pea-size berries, that is never observed in the reproductive development of grapevine plants (Figure 1c,d).

Scale bars: 100 μ m in (a–c); 250 μ m in (d–f).

In addition, many RRM flowers displayed alterations of the third and fourth whorls, showing partial transformation of stamens into petaloid structures (Figure S1). Finally, some flowers developed additional internal flowers, probably as a result of the lack of determination of flower meristems (Figure 1e). These abnormal RRM flowers resulted in an unusual opening of the flower from the top of the calyptra (Figures 1e and S1), in contrast to the wild-type flower opening, where the calyptra detaches from the receptacle (Figure 1f).

The early development of RRM and Carignan inflorescences was analysed through optical and scanning electron microscopy, from the initiation of the inflorescence meristem during latent bud organogenesis at year $n - 1$ to flower meristem initiation at year n . As the RRM plants present a delay in inflorescence differentiation, equivalent bud phenological stages were considered for comparison. During early latent bud formation, RRM plants displayed a similar pattern and timing of inflorescence initiation as Carignan plants (data not shown). However, by the end of inflorescence formation within latent buds, the RRM inflorescences (Figure 2a) did not exhibit the typical conical structure formed by inflorescence branch meristems in Carignan plants (Figure 2b). Later, at bud burst, the RRM inflorescence structure did not show a significant evolution (Figure 2c), whereas Carignan inflorescences already showed the initiation of flower meristems (Figure 2d). At stage IS1, a few RRM inflorescences were just beginning to initiate flower meristems. However, most inflorescence branch meristems were still generating additional inflorescence branches, preventing the differentiation of terminal flowers (Figure 2e). At the same stage, Carignan inflorescences had already formed flowers displaying three well-differentiated whorls: sepals, petals that had begun to fuse, and developing anthers with filaments not yet visible (Figure 2f). Thus,

the RRM inflorescences show a delay in the initiation of flower meristems and floral organ differentiation, which is related to the reiterative production of additional inflorescence meristems.

Cluster structure. To characterize the differences in cluster structure between RRM and Carignan plants, we performed a quantitative analysis of their architecture. A schematic diagram of representative clusters for each genotype is shown in Figure 3. Carignan clusters only branched to generate axes of order 2 and 3 (A2 and A3), whereas RRM inflorescences displayed higher branching, producing axes of

Figure 3. Schematic diagram representing the architecture of Carignan (CAR) and reiterated reproductive meristem (RRM) clusters.

A, axis; A1, main axis; A2–A4, axes from orders 2 to 4; BG, berry groups; S, segment. Berry groups are represented in green. Lengths of segments have been computed from the measured length of axes assuming that all the segments have the same length.

Trait	Definition	CAR	RRM	P value ^a
Axis type	% of A2	76.69 (16.39)	17.92 (4.75)	*
	% of A3	23.31 (16.39)	63.91 (10.95)	*
	% of A4	–	17.54 (14.31)	–
	% of A5	–	0.63 (1.4)	–
Branching	Axis number	17.17 (7.63)	126.4 (46.55)	*
Axis length	Cumulative axis length	26.18 (7.19)	152.8 (47.52)	*
	Axis length/A1 length	2.47 (0.48)	11.87 (4.88)	**
Axis density	Axis number/cumulative axis length	0.66 (0.24)	0.82 (0.1)	ns
Branching rate	Axis number/A1 length	1.66 (0.68)	9.81 (4.48)	**

Mean value (SD) obtained from the analysis of six Carignan (CAR) and five reiterated reproductive meristems (RRM) clusters: A1, main axis of the cluster; A2, order-2 axes; A3, order-3 axes; A4, order-4 axes; A5, order-5 axes; –, no data.

^aStatistical significance of mean differences between CAR and RRM according to a Welch's *t*-test:

*highly significant ($P \leq 0.01$); **significant ($0.01 < P \leq 0.05$); ns, non-significant ($P > 0.05$).

up to order 5 (A5). As a whole, RRM clusters exhibited a number of axes, and a cumulative axis length that was on average seven and five times longer than in Carignan clusters, respectively (Table 1). The cumulative axes length related to the main cluster axis length remained significantly higher in RRM clusters than in Carignan (Table 1). However, axes density (axis number/cumulative axis length) in the mutant and in the wild type were found to be similar (Table 1), in agreement with the higher branching rate (axis number/A1 length) of RRM clusters (Table 1). Consequently, at ripening stage RRM bunches appeared much larger and less compacted than Carignan ones (Figure S1).

Tendrils phenotype. The Vitaceae tendrils have a common ontogenetic origin with inflorescences, and could be considered as sterile reproductive structures adapted to climbing (Boss *et al.*, 2003). RRM plants also displayed a differential phenotype on tendrils, which were more branched than in Carignan plants (Figure 4a,b). Carignan tendrils generally have two (56%) or three (44%) branches, whereas

in RRM plants, 86% of tendrils develop three or more branches. Furthermore, RRM plants frequently exhibited leaf/tendrils or shoot/tendrils substitutions that are rare in Carignan plants (Figures S1 and 4c). In addition, intermediate leaf/inflorescence structures were also observed in RRM plants (Figure 4d).

Transcriptional analysis of the RRM phenotype

Considering that the RRM phenotype probably appeared as a consequence of a single mutation in a given cell line, a plausible hypothesis was that the mutation had a dominant effect on the phenotype. Based on this hypothesis we reasoned that the analyses of transcriptional changes associated with phenotype expression could provide information on the gene(s) altered in the somatic variant. We performed a transcriptional analysis of Carignan and RRM inflorescences at two different times of development, on 18 April 2006 and 27 April 2006. Given the delayed development of RRM inflorescences with respect to Carignan ones, at the first date both inflorescences were at stage IS1, whereas at

the second date RRM inflorescences were at stage IS2, and Carignan ones were at stage IS3.

Using the commercially available Grape Affymetrix Gene-Chip® (Santa Clara, CA), containing 16 436 grapevine probe sets, only 58 probe sets were found to be differentially expressed between Carignan (CAR) IS1 and RRM IS1, and/or

between CAR IS3 and RRM IS2 (Figure 5a; Table S2). The eight genes exhibiting the highest under-representation in RRM inflorescences encoded transcriptional factors belonging to the YABBY protein family (*abnormal floral organs*, *AFO*), as well as several homologs of MADS-box genes *SEPALLATA 1* (*SEP1*), *SEP3*, *APETALA 3* (*AP3*), *PISTILLATA*

(*PI*), *AGAMOUS* (*AG*)/*SHATERPROOF* (*SHP*), *AG/AGL11* and *AGL6/AGL13*. Their underexpression in the IS1 and IS2 stages of RRM inflorescence could be a consequence of the lack of flower organ differentiation in these inflorescence stages of the somatic variant, as most of them have been shown to be involved in the specification of flower organ identity. Interestingly, two genes encoding proteins involved in the regulation of flowering induction, phase transition and inflorescence development were overexpressed in the RRM inflorescences: *VvSVP1*, a homolog of Arabidopsis *SHORT VEGETATIVE PHASE* MADS-box gene, and *VvTFL1A*, homologous with Arabidopsis *TERMINAL FLOWER 1*.

The results of the transcriptional profiling experiment were validated for two RRM upregulated (*VvSVP1* and *VvTFL1A*) and one downregulated (*VvPI*) genes using qRT-PCR on the same samples, plus one additional RNA sample corresponding to stage IS3 of RRM inflorescences (harvested on 30 May 2006). RRM inflorescences exhibited no detectable expression of *VvPI* during stages IS1 and IS2 (Figure 5b). However, at stage IS3, RRM inflorescences showed similar levels of *VvPI* expression as CAR ones. The qRT-PCR experiment also confirmed the high overexpression of *VvTFL1A* at all stages of RRM inflorescence development, whereas *VvTFL1A* was hardly detectable in CAR inflorescences (Figure 5c). Finally, *VvSVP1* was overexpressed in RRM plants at all inflorescence stages analyzed (Figure 5d). The biological roles assigned to these genes in Arabidopsis were related to a delay in flowering transition (*SVP*), as well as phase transition establishment and inflorescence architecture (*TFL1*), which made them candidates to be responsible for the RRM phenotype.

Genetic analysis of the RRM phenotype

To test the hypothesis on the putative role of *VvTFL1A* or *VvSVP1* in the origin of the RRM phenotype, we analyzed the segregation of this phenotype as well as that of the gene allelic variants in selfed progenies derived from RRM and CAR plants. Grapevine plants grown from seeds can take between 3 and 5 years to produce inflorescences and fruits. For this reason, plants were phenotyped on the basis of tendril morphology (see Experimental procedures). The RRM phenotype could be observed in the selfed progeny of RRM plants, indicating that the causal mutation was present in the L2 cell layer, which gives rise to the gametes. Only 23 out of 34 segregating plants could be phenotyped, and their phenotypic segregation fitted a 3:1 Mendelian segregation model, as expected for the presence of a single dominant mutation in a heterozygous state in the RRM somatic variant ($\chi^2 = 1.75$, $P = 0.18$) (Table 2). Dominance of the RRM phenotype was in agreement with the hypothesis that it could result from the overexpression of *VvTFL1A*, *VvSVP1* or other genes detected in the transcriptional profiling.

Table 2 Segregation of reiterated reproductive meristem (RRM) phenotype and *VvTFL1A* and *VvSVP1* genotypes in the selfed progeny of the RRM somatic variant

Genotype	N	WT*	RRM*	ND*
<i>SVP1a/SVP1a</i>	8	1	5	2
<i>SVP1a/SVP1b</i>	17	1	8	8
<i>SVP1b/SVP1b</i>	9	1	7	1
Total	34	3	20	11
<i>TFL1Aa/TFL1Aa</i>	15		13	2
<i>TFL1Aa/TFL1Ab</i>	14		7	7
<i>TFL1Ab/TFL1Ab</i>	5	3		2
Total	34	3	20	11

*Phenotypes were scored as wild-type (WT), RRM or not determined (ND), following the procedure described in Experimental procedures.

Contrary to plant model systems such as Arabidopsis or tomato (*Solanum lycopersicum*), grapevine plants are highly heterozygous at most of their loci. Therefore, we analyzed the co-segregation of the RRM phenotype with the two alleles (named as a and b) of *VvTFL1A* and *VvSVP1* present in CAR (Table 2). When considering *VvSVP1*, which in grapevine is located on linkage group 7 (IASMA, <http://genomics.research.iasma.it/iasma/>), the three expected genotypes segregated following a 1:2:1 model ($\chi^2 = 0.058$, $P = 0.97$), as expected for co-dominant markers. No *VvSVP1* allele was found to co-segregate with the RRM phenotype. Regarding the *VvTFL1A* gene, located on linkage group 6 (R. Velasco, personal communications), the observed genotype segregation was distorted, and did not fit the 1:2:1 model ($\chi^2 = 6.94$, $P = 0.03$). However, there was a complete association of the RRM phenotype with the presence of the *VvTFL1Aa* allele in either the homozygous or heterozygous state, whereas all plants with a wild-type tendril phenotype were homozygous for the *VvTFL1Ab* allele. In fact, among the 11 individuals that showed the most extreme leafy tendril phenotype, eight were homozygous for *VvTFL1Aa*. As plants homozygous for the *VvTFL1Aa* allele in the segregating progeny from CAR did not display the RRM phenotype, we hypothesized that the *VvTFL1Aa* allele should have mutated in the L2 cell layer of the CAR plant that gave rise to the somatic variant displaying the RRM dominant phenotype.

The RRM phenotype is caused by a class-II transposon insertion

Transposon characterization. In order to identify the molecular change responsible for the RRM phenotype, we sequenced 4308 bp for each *VvTFL1A* allele, including 3104 and 1204 bp before and after the ATG sequence, respectively. The two CAR alleles showed 98% of sequence identity with the corresponding Pinot Noir genome sequence (Jaillon *et al.*, 2007). The *VvTFL1A* coding region included four exons of 201, 63, 41 and 217 bp, separated by three introns of 83, 467 and 107 bp, as previously described

Figure 6. Sequence analysis of the *VvTFL1A* locus.

(a) Genomic organization of the *VvTFL1A* locus in Carignan. Exons are represented by yellow boxes. Polymorphism between *VvTFL1Aa* and *VvTFL1Ab* alleles are indicated by pink and blue lines for nucleotide substitutions and INDELs, respectively. Amino acid changes between both alleles are also indicated. The vertical arrow indicates the position of the transposon insertion in the reiterated reproductive meristem (RRM) *VvTFL1Aam* allele. The horizontal arrow marks the position of the ATG start codon.

(b) Genotype of *VvTFL1A* alleles in Carignan (CAR), RRM and selfed plants using TFL1-F4/R4 primers. The allele *VvTFL1A* combination is indicated in the second line. Lane 11 shows the bands amplified in a plant carrying a revertant (*VvTFL1Aar*) allele. A 5-μl portion of each PCR product was loaded onto a 0.7% agarose gel. Line 1 contains the 1-kb DNA ladder from Invitrogen (<http://www.invitrogen.com>).

(c) Organization of the *VvTFL1Aam* and *VvTFL1Aar* mutant alleles found in the RRM-derived plants. The *VvTFL1Aam* allele bears a 5.2-kb transposon insertion at position -305 bp, with respect to the ATG start codon. Target site duplications (TSDs), terminal inverted repeats (TIRs) and the transposase coding sequence are schematized. *VvTFL1Aar* has lost the transposon insertion, and presents an 8-bp insertion corresponding to the TSD or transposon footprint.

(Carmona *et al.*, 2007). Twenty seven polymorphisms differentiated the two *VvTFL1A* allele sequences present in CAR, including four INDELs. Among them, three SNPs were found in the coding region, one in exon 1 and two in exon 4, giving rise to two amino acid substitutions (Figure 6a).

As expected, the *VvTFL1Ab* allele sequences were identical in homozygous plants derived from the RRM somatic variant, or from CAR selfing. Regarding *VvTFL1Aa*, its sequence in homozygous plants derived from RRM selfing was also identical to that obtained in CAR-derived plants, with the exception of a region upstream of the ATG, where we detected the presence of a new approximately 5-kb insertion not present in the CAR *VvTFL1Aa* allele. This allele was detected in all the individuals showing the RRM phenotype, and was named *VvTFL1Aam*. All plants genotyped as homozygous for the *VvTFL1Aam* mutant allele in the RRM-selfed progeny showed the unique presence of this insertion (Figure 6b). However, we detected one plant genotyped as homozygous for *VvTFL1Aam* in which a PCR amplicon corresponding in size to the non-mutant allele was also amplified. This unexpected amplicon was sequenced and found to correspond to a new allele, *VvTFL1Aar*, that had lost the inserted DNA, and contained a short tandem duplication of 8 bp (Figure 6b,c). Thus, some cells of the leaves used to extract DNA in this plant had lost the transposon insertion in one of the two copies of the gene.

The complete sequencing of the inserted DNA revealed a 5232-bp sequence, flanked by an 8-bp target site duplication

(TSD) and 22-bp terminal inverted repeats (TIRs) (CA-AGGATTGAAATATCGGTAA), typical of class-II transposable elements (Figure 6c). BLASTX sequence comparisons with sequence databases showed that the sequenced fragment has a high sequence similarity with *Arabidopsis hAT* transposons (NP188371). This element was named *Hatvine1-rrm*, and showed the highest identity (99.9%) with a Pinot Noir sequence localized on chromosome 5 (scaffold 64, position 1 431 877–1 437 144; Genoscope, <http://www.cns.fr>). The closest homolog to the predicted protein encoded by *Hatvine1-rrm* is the *Vitis* protein CAN71355, which contains the *hAT* family dimerization domain conserved in transposase-like proteins (Marchler-Bauer *et al.*, 2007). However, no expressed sequence tag (EST) corresponding to this transposase could be found in grapevine databases. Therefore, the RRM phenotype, associated with *VvTFL1A* overexpression, seems to be related to the insertion of a *Hatvine1* element in the promoter region of *VvTFL1A*. Although we could not confirm that this element is an autonomous element encoding a functional transposase, it mobilizes in the genome of CAR, and has generated at least two new *VvTFL1A* alleles (*VvTFL1Aam* and *VvTFL1Aar*).

Molecular effect of *Hatvine1-rrm* insertion. Transposon insertions frequently cause loss-of-function alleles. However, the dominant nature of the RRM phenotype suggested the presence of a gain-of-function mutation, in agreement

Figure 7. *VvTFL1A* expression along the shoot. *VvTFL1A* qRT-PCR expression analysis along Carignan (CAR) and reiterated reproductive meristem (RRM) shoots. Numbers correspond to the node position from the apex. Expression values were normalized with *EF1alpha* and expressed as relative abundance (%).

Error bars: SDs for technical triplicates.

with *VvTFL1A* overexpression in RRM inflorescences. To understand the effect of the *Hatvine1-rrm* insertion, we analyzed its consequences on *VvTFL1A* expression. We first determined the organ-specific expression of *VvTFL1A* in the apical part of the shoot using qRT-PCR. *VvTFL1A* expression was detected in the CAR apex and the first shoot internodes, whereas it was undetectable in developing leaves and tendrils of the shoot apical region (Figure 7). By contrast, RRM shoots exhibited much higher *VvTFL1A* expression than CAR in apex and internodes, but also in first developing leaves and tendrils. Both in CAR and RRM plants *VvTFL1A* expression was reduced with distance from the apex. Thus, the transposon insertion seemed to be related to an enhancement of *VvTFL1A* expression in the shoot apical organs, but its expression remained under developmental control.

We hypothesized that if the transposable element was the cause for the observed overexpression of *VvTFL1A* in the apical parts of the shoot, this expression should be allele-specific, and restricted to the allele carrying the insertion in its promoter region. To test this hypothesis, we developed allele-specific qRT PCR assays and analyzed the expression of both *VvTFL1A* alleles in the first shoot internode of heterozygous plants. As shown in Figure 8, the *VvTFL1Aa* allele was overexpressed 10-fold in RRM and derived selfed plants when compared with CAR (Figure 8b), whereas no significant differences were detected between expression levels of the *VvTFL1Ab* allele (Figure 8c). This result supports the hypothesis that the transposon insertion is related to *VvTFL1A* overexpression.

To analyze the transcriptional initiation site (TIS) of each allele, we performed 5' rapid amplification of cDNA ends (RACE) of *VvTFL1Aam*, *VvTFL1Aa* and *VvTFL1b* transcripts

in plants homozygous for each allele, derived from selfing of either RRM or CAR genotypes. These experiments identified the same TIS position for the three different

Figure 8. *VvTFL1A* allelic expression.

(a) Total *VvTFL1A*, (b) *VvTFL1Aa* and (c) *VvTFL1Ab* qRT-PCR expression in internode stem tissue of Carignan (CAR), reiterated reproductive meristem (RRM), and of CAR- and RRM-selfed segregants heterozygous for the *VvTFL1A* locus. Expression values were normalized with *EF1alpha*, and were expressed as relative abundances (%). To facilitate comparison, expression in RRM and RRM-selfed plants were arbitrarily fixed to 100%.

Error bars: SDs for biological duplicates.

alleles (*a*, *b* and *am*), 83 bp upstream of the ATG, indicating that *VvTFL1Aam*-specific overexpression did not result from the use of a new TIS related to the *Hatvine1-rrm* insertion. Therefore, these results suggest that the overexpression of the *VvTFL1Aam* allele is caused by an enhancer effect resulting from the close insertion of *Hatvine1-rrm* in its promoter region.

DISCUSSION

The RRM phenotype is associated with the enhancement of *VvTFL1A* expression caused by a class-II transposon insertion

Here, we report on the identification of the molecular basis of the RRM phenotype, first detected as a spontaneous sport in grapevine plants of cultivar CAR (Chatelet *et al.*, 2007), which has a large effect on inflorescence and fruit cluster development. Genetic analyses in selfed progenies of the original somatic variant showed that the phenotype was transmitted to the progeny as a single dominant trait. Furthermore, a comparative morphological and transcriptional analysis performed in CAR and RRM plants permitted the identification of two overexpressed genes (*VvTFL1A* and *VvSVP1*) as candidates to be responsible for the RRM phenotype. Co-segregation of a specific *VvTFL1Aa* allele with the RRM phenotype, and the identification of the *Hatvine1-rrm* transposon inserted in position –305 bp of its promoter region in RRM plants suggested that this insertion was the origin of the phenotypic alteration. This hypothesis is strongly supported by the fact that overexpression of *VvTFL1A* in the somatic variant is allele-specific, and only affects the *VvTFL1Aam* allele that carries the transposon insertion in *cis*. Still, we cannot completely exclude the unlikely possibility that another linked mutation with a *cis* effect on *VvTFL1A* expression could be the origin of the RRM phenotype.

Hatvine1-rrm belongs to the family of *hAT* transposable elements recently characterized in grapevine (Benjak *et al.*, 2008). The *hAT* superfamily is widely distributed in eukaryotes (Rubin *et al.*, 2001) and is the most prevalent transposon class in the grapevine genome, with over 1500 related sequences (Benjak *et al.*, 2008). The element identified in the *VvTFL1Aam* promoter belongs to the subfamily *Hatvine1*, and its presence demonstrates the existence of active transposition for members of this subfamily in the grapevine genome. Transposition activity is supported by the detection of both new insertion events, i.e. the one described in the *VvTFL1Aam* allele, and excision events, which leave behind the 8-bp duplication footprint, as shown by the generation of the *VvTFL1Aar* allele. The transposase open reading frame (ORF) in this *Hatvine1* element seems to be potentially complete, and able to encode a putative functional protein. However, *Hatvine1-rrm* could also be mobilized by a master copy acting in *trans*. Insertion of the *Hatvine1-rrm* element

caused a dominant effect associated with the overexpression of the *VvTFL1Aam* tagged allele. Overexpression of this allele was not constitutive, but took place in a developmental-specific manner, being observed in young developing organs along the stem, including the shoot apex, leaves, internodes and tendrils, and progressively decreasing in older organs. As the insertion orientation placed the *Hatvine1* transposase ORF opposite to the *VvTFL1A* ORF, both genes should be expressed through independent transcriptional units. Furthermore, our experimental results show that the transcription start of the *VvTFL1Aam* allele in RRM is the same as that of the *VvTFL1Aa* allele in CAR. All these data support the conclusion that *Hatvine1-rrm* enhances the expression of the *VvTFL1Aam* allele, either by enhancing transcription initiation at its own transcription start site, or alternatively by disrupting a repressor binding site on the *VvTFL1Aam* promoter. However, no information is available on the existence of such sites for the promoter of *TFL1* homologs in other species. The wide literature on class-II transposable elements in plants reports frequent cases of insertion in 5' upstream gene regulatory sequences, which generally negatively affect gene expression (Yang *et al.*, 2005; Xu *et al.*, 2007; Zhai *et al.*, 2008), and there are only a few examples in which transposon-mediated sequence rearrangements have generated new gene expression patterns (Lister *et al.*, 1993; Kloeckener-Gruissem and Freeling, 1995). Positive regulation or enhancement of gene expression mediated by transposable elements located not necessarily in 5' upstream regions has been observed (Bradley *et al.*, 1993; Greene *et al.*, 1994) as a result of *cis*-enhancing effects, depending on a *trans*-acting active transposon (Greene *et al.*, 1994), or probably as a result of sequences carried over by transposable elements that could act as positive regulatory motifs (Dooner and Weil, 2007). Mechanisms of *cis*-activation tagging promoted by endogenous transposable elements, like the one described for *Hatvine1-rrm*, could generate gain-of-function mutations, and consequently new somatic phenotypes in perennial species. These phenotypes could be directly exposed to natural selection, providing genetic variation for adaptation along the vegetative cycle of perennial species, which could also be transmitted to the next sexual and/or asexual generations. Further analyses will be required to test these possibilities.

Role of *VvTFL1A* in grapevine development

The RRM phenotype is associated with the enhanced expression of grapevine *VvTFL1A* in the apical shoot organs. *VvTFL1A* is the closest grapevine homolog to Arabidopsis *TERMINAL FLOWER 1* (*TFL1*) (Bradley *et al.*, 1997), *Antirrhinum CENTRORADIALIS* (*CEN*) (Bradley *et al.*, 1996), pea (*Pisum sativum*) *DETERMINATE* (*DET*) (Singer *et al.*, 1990), tomato *SELF-PRUNING* (*SP*) (Pnueli *et al.*, 1998), tobacco (*Nicotiana tabacum*) *CET* (Amaya *et al.*, 1999) or *Lolium*

perenne *LpTFL1* (Jensen *et al.*, 2001), encoding a protein similar to animal phosphatidylethanolamine-binding proteins (PEBPs), the molecular function of which is not completely understood (Keller *et al.*, 2004; Odabaei *et al.*, 2004), although it seems to be associated with trafficking to protein storage vacuoles (Sohn *et al.*, 2007). The analyses of mutant phenotypes in *Arabidopsis*, *Antirrhinum* and in other species support a biological function of this gene in the control of the length of plant developmental phases, as well as in the maintenance of indeterminate growth of inflorescence meristems (Schultz and Haughn, 1991; Bowman *et al.*, 1993). Consequently, loss-of-function mutants commonly show significantly shorter vegetative phases than wild-type plants, as well as rapid differentiation of terminal flowers in place of inflorescence meristems (Shannon and Meeks-Wagner, 1991; Alvarez *et al.*, 1992; Schultz and Haughn, 1993; Bradley *et al.*, 1997). In addition, overexpression of these genes in transgenic plants generates highly branched inflorescence phenotypes, resulting from a delay in the differentiation of flowers, as well as a delay in developmental phase transitions (Ratcliffe *et al.*, 1998).

Three *VvTFL1*-related genes have been identified in grapevine under the names *VvTFL1A*, *VvTFL1B* and *VvTFL1C* (Carmona *et al.*, 2007). Interestingly, overexpression of *VvTFL1A* in transgenic *Arabidopsis* plants had similar effects as those described for the ectopic expression of *TFL1* (Ratcliffe *et al.*, 1998), in terms of increasing inflorescence branching and delaying the initiation of flower meristems (Boss *et al.*, 2006; Carmona *et al.*, 2007). Furthermore, the RRM phenotype linked to *VvTFL1A* overexpression in grapevine is also coincident with the phenotype described in *Arabidopsis*. The effects of enhanced expression of *VvTFL1A* could be mediated in part by *VvSVP1*, also overexpressed in the RRM somatic variant. This MADS-box gene was identified in *Arabidopsis* as encoding a dosage-dependent repressor of flowering (Hartmann *et al.*, 2000; Lee *et al.*, 2007; Liu *et al.*, 2007), and directly represses transcription of the floral integrator *SOC1* gene in the shoot apex (Li *et al.*, 2008). Constitutive overexpression of *TFL1* in transgenic *Arabidopsis* causes a delay in flowering time as a result of an extension of the vegetative phase (Ratcliffe *et al.*, 1998). However, it is not clear whether *TFL1* produces this effect through the positive regulation of *SVP* expression in *Arabidopsis*.

Altogether, the available information indicates that initiation of lateral shoot structures in grapevine requires a certain level of *VvTFL1A*, as suggested by previous expression analyses (Joly *et al.*, 2004; Boss *et al.*, 2006; Carmona *et al.*, 2007), but also indicates that *VvTFL1A* should be progressively downregulated to complete flower and tendril differentiation. This hypothesis on the role of *VvTFL1A* in grapevine would predict that loss-of-function mutations or transgenic silenced plants would generate minimal lateral organs, such as tendrils or inflorescences, with no ramifica-

tion, and a rapid differentiation of flowers, possibly in a single dichasium structure. Further experiments will be required to confirm this prediction.

Grapevine fruit cluster size and shape is initially determined by the structure of inflorescence and its elongation during cluster growth (Shavrukov *et al.*, 2003). Furthermore, the number of flowers formed per inflorescence meristem, together with the success of pollination and fruit set, determine the number of fruits that, depending on their size, will also affect the cluster compactness. Very little is known about the genetic control of cluster size and shape. As shown by the results of the cluster structural analysis in RRM and CAR plants, changes in *VvTFL1A* expression of the level observed in the RRM somatic variant could affect axis length and branching pattern of the cluster, and consequently its size and shape, by increasing or decreasing the order number of branch axes, and their total number. *TFL1* has been proposed to play a key role in the evolution of inflorescence architecture (Prusinkiewicz *et al.*, 2007), and *VvTFL1A* could play a relevant role in the control of this trait in grapevine, and consequently on cluster structure. The large differences existing in terms of cluster size and shape between wild (*V. vinifera* ssp. *sylvestris*) and cultivated (*V. vinifera* ssp. *sativa*) grapevine genotypes suggest that cluster traits have been selected during the domestication of grapevine (This *et al.*, 2006). Further experiments will be required to determine the participation of *VvTFL1A* in the control of genetic variation for cluster size and shape in grapevine, and to test whether specific *VvTFL1A* variants have been selected during the domestication process.

EXPERIMENTAL PROCEDURES

Plant materials

The RRM somatic variant appeared as a sport of the grapevine cultivar Carignan (*V. vinifera* L.), also known by its synonyms Cariñena and Mazuelo. Their genetic identity was previously confirmed (Chatelet *et al.*, 2007), and both the somatic variant and the original CAR plant are conserved in the grapevine collection at the INRA Domaine de Vassal (<http://www1.montpellier.inra.fr/vassal/>). Both genotypes were propagated in containers as woody canes taken from the original plants. Herbaceous buds (HBs) were sampled in April between the 15th and 21st nodes from the basis of the shoot, winter buds (WBs) were collected in December between the fourth and 10th nodes from the basis of the shoot, and buds at budburst (BBs) corresponded to the buds where first leaf tissue was visible. Inflorescence developmental stages were identified as described in Sreekantan *et al.* (2006). They corresponded to very young inflorescences (no single flower visible) emerging from the bud (IS1), clearly separated from the vegetative axis (IS2) and showing the first single flower (IS3). Vegetative organs were collected from shoots with more than six nodes separating the apex, tendrils or tendril-like organs, leaves and internodes.

To study the genetic control of the RRM phenotype we generated two segregating populations by selfing the wild-type CAR plant (CAR-selfed progeny), as well as the RRM somatic variant (RRM-selfed progeny), further established in pots in the glasshouse. Plants were phenotyped for alterations observed on tendrils. Plants

with the presence of leafy tendrill structures and tendrils with more than three branches were classified as the RRM type because of the lack of those phenotypes in the selfed CAR segregating plants. Only three plants in the control segregating population produced three-branched tendrils at low frequency. In this context, plants that developed more than 50% of three-branched tendrils per shoot were classified as the RRM phenotype in the RRM segregating progeny. To avoid erratic phenotyping, plants with less than 50% of three-branched tendrils were not classified (not determined), and were kept for further analysis. Finally, plants that only developed two-branched tendrils were classified as the wild type. Phenotype was based on the observation of a minimum of six tendrils per shoot, and was repeated in at least two shoots for 12 and 11 individuals from CAR- and RRM-selfed progenies. The goodness-of-fit to expected segregation ratios was assessed by a chi-square test.

Microscopy analysis

For scanning electron microscopy (SEM) and histological analyses, samples were processed as described by (Chatelet *et al.*, 2007).

Analysis of cluster architecture

To study cluster architecture, a sample of six wild-type and five mutant clusters were selected at ripening stage. The multiscale coding method defined by Godin *et al.* (1997) was applied to model cluster architecture into a multiscale tree graph (MTG). Three organization levels were considered: (1) rachis (R), (2) axes (A), and (3) segments (S) and berry groups (BG). Axis length was scored and integrated as attributes of A. Based on these MTGs, several architectural traits were extracted using AMAPMOD (Godin and Guédon, 2003). Topological differences between the two genotypes were illustrated by schematic 3D representations of the clusters using the GEOM module of AMAPMOD (Godin and Guédon, 2003), and are represented in two dimensions in Figure 3.

Gene expression analyses

Grapevine RNA was extracted following the protocol of Reid *et al.* (2006), and further purified with Qiagen RNeasy Mini columns (<http://www.qiagen.com>), including a DNase treatment, as recommended by the manufacturer.

Microarrays. Transcriptional profiling was performed on early inflorescence developmental stages for the CAR and the RRM plants. Three biological replicates were processed per experiment. Synthesis of labeled probes, hybridization and scanning of the GeneChip® *Vitis vinifera* (Grape) Genome array v1.0 (Affymetrix®, <http://www.affymetrix.com>) were carried out at the Genomics Service of the CNB (<http://www.cnb.uam.es/~genomica/>). Microarray data were first normalized using the Affymetrix normalization package available on GEPAS (<http://gepas.bioinfo.cipf.es/>). Normalization included Robust MultiArray Average (RMA) for background correction (Irizarry *et al.*, 2003), perfect match (PM) correction (Li and Wong, 2001), quantile array standardization (Bolstad *et al.*, 2003) and finally median polish procedure (Tukey, 1977). A Student's *t*-test was performed on RMA expression values from inflorescence samples harvested at the same date in RRM and CAR: CAR IS1 versus RRM IS1, and CAR IS3 versus RRM IS2. A multiple-test correction was applied to the *P* value of the *t*-statistics to adjust the false discovery rate (Benjamini and Hochberg, 1995). Genes with an adjusted *P* < 0.05 and an expression change fold ratio of 1.5 or more between RRM and CAR were selected for further analysis. The normalized data set was clustered via hierarchical clustering using the average linkage method and the

Pearson uncentered distance metric using GENESIS 1.7.2 (Sturn *et al.*, 2002).

qRT-PCR. Analyses were performed as described by Fernandez *et al.* (2007) using an ABI PRISM 7300 Sequence Detection System (Applied Biosystems, <http://www.appliedbiosystems.com>) with SYBR® Green to detect dsDNA synthesis. Specific primers were designed in the 3' untranslated region of *VvTFL1A* (AF378127) and *VvSVP1* (BQ794993) (Table S1: TFL1F, TFL1R, SVPF and SVPR). Amplification of *VvPI* (DQ059750) and *VvEF1alpha* (BQ799343) genes was performed using previously described primers (Fernandez *et al.*, 2007).

Allele-specific expression for *VvTFL1A* was analyzed by SYBR Green-based qRT-PCR during 30 cycles of PCR amplification. Forward-specific primers for allelic discrimination assays were designed as recommended by Gupta *et al.* (2005). Primer sequences are available in Table S1 (TFL1R, 1095FA and 1095FC). Genomic DNA and cDNA from homozygous segregant individuals were used to verify the allelic discrimination efficiency in control experiments.

5' RACE. For the 5' RACE, we used 1 µg of total RNA of both *VvTFL1Aa* and *VvTFL1Ab* homozygous individuals of the CAR- and RRM-selfed progenies using the SMART RACE cDNA Amplification kit (Clontech, <http://www.clontech.com>), as recommended by the manufacturer. TFL1R primer (Table S1) was used as gene-specific primer 1 (GSP1). 5'-RACE products were purified and sequenced with TFL1R primer, as described below.

Molecular genetics analyses

Genomic DNA was extracted from young leaves using the Qiagen DNeasy Plant Mini kit (Qiagen), as recommended by the manufacturer.

Genotyping. Cleaved amplified polymorphic site (CAPS) markers were used to detect SNP 1095 of *VvTFL1A* using *ApoI*, and SNP 3332 of *VvSVP1* using *TaqI*. Primers are listed in Table S1 (TFL1F¹⁰⁹⁵, TFL1R, SVP1F³³³² and SVP1R³³³²).

Sequencing. To sequence the different alleles of *VvTFL1A*, six sets of specific primers were designed to amplify 700–900-bp overlapping sequences in the promoter and ORF of *VvTFL1A* (chromosome un-random, scaffold 87, position 137 062 691–137 067 029; Genoscope, <http://www.genoscope.cns.fr/spip/Vitis-vinifera-e.html>) (Table S1: TFL1-F1-F6 and TFL1-R1-R6). PCR amplifications were performed from 10 to 20 ng of grape genomic DNA using the AmpliTaq DNA polymerase (Applied Biosystems), as recommended by the manufacturer. The transposon amplicon was amplified using TFL1-F4 and TFL1-R4 primers. PCR amplifications were performed from 15 to 30 ng of grape genomic DNA using the LongRange PCR Enzyme mix (Qiagen), as recommended by the manufacturer. PCR products were treated with Exosap-IT reagent, as recommended by the manufacturer, and were sequenced at the Genomic Service of the Parque Científico de Madrid, in an ABI prism 3730 DNA sequencer (Applied Biosystems).

The transposon was first sequenced with TFL1-F4 and TFL1-R4, giving the 5' and 3' end transposon sequence. The identification of closely related sequences was made against the Genoscope Blat server, to find a homolog reference sequence. Thereafter, 20 primers were defined along the reference sequence and used to sequence the *Hatvine1-rrm* transposon product. In total, 17 primers were used to sequence 3X transposon coverage (Table S1: TE-F1-F10 and TE-R1-R7). Base calling, quality trimming and alignment of

ABI chromatograms was performed using SeqScape 2.5. Sequence polymorphisms were verified manually.

ACKNOWLEDGEMENTS

The authors want to thank Diego Lijavetzky for help with Affymetrix chips analysis, Philippe Chatelet for helping with inflorescence fixations, Gilbert Lopez and the CNB glasshouse facility staff for the care of the plants, and the CNB Genomics service staff for Affymetrix GeneChip hybridization experiments. Francisco Madueño and Desmond Bradley are acknowledged for their critical reading of the manuscript, and we thank Carlos Alonso Blanco and María José Carmona for helpful discussions. This research was supported by grants BIO2005-07612 and BIO2008-03892 from the Spanish Ministry for Science and Innovation, and by funds from the INRA Plant Breeding and Genetics Department.
