Abstract

Arabidopsis thaliana peptide deformylase PDF1B was expressed in tobacco chloroplasts using spectinomycin as the selective agent. The foreign protein accumulated in chloroplasts (6% of the total soluble protein) and was enzymatically active. Transplastomic plants were evaluated for resistance to the peptide deformylase inhibitor actinonin. *In vitro* seed germination in the presence of actinonin and *in planta* application of the inhibitor demonstrated the resistance of the transformed plants. In addition, transgenic leaf explants were able to develop shoots via organogenesis in the presence of actinonin. However, when the combination of the *PDF1B* gene and actinonin was used as the primary selective marker system for chloroplast transformation of tobacco, all developed shoots were escapes. Therefore, under the experimental conditions tested, the use of this system for plastid transformation would be limited to function as a secondary selective marker.

Introduction

The availability of suitable selective marker genes and selective agents is critical for the development of efficient plant transformation protocols. The most widely used selective system for plastid transformation is the *aadA* gene from *E. coli* that confers resistance to spectinomycin and streptomycin (Svab and Maliga, 1993). Spectinomycin selection is very effective and yields between 0.5 and 5 transplastomic lines per bombarded leaf in tobacco (Maliga, 2004). Kanamycin resistance, conferred by the bacterial *nptII* (Carrer et al., 1993) or *aphA-6* (Huang et al., 2002) genes, was also appropriate for the recovery of plastid transformants, despite the lower overall transformation efficiency compared to that of the *aadA* gene. The tobacco feedback-insensitive anthranilate synthase α -subunit, which catalyses the first reaction in the tryptophan biosynthetic pathway, has been successfully used for the recovery of tobacco transplastomic plants (Barone et al., 2009). The tryptophan analogue 7-methyl-DL-tryptophan was used as the selective agent. With this selection scheme, one resistant line was obtained out of 20 bombarded leaves. Recently, the chloramphenicol acetyl transferase gene *cat* has been reported as a new selectable marker for plastid transformation of tobacco (Li et al., 2010). Although selection with *cat*, in the presence of chloramphenicol, was less efficient than with *aadA*, the *cat* marker offers the advantage of not producing spontaneous antibiotic-resistance mutants. In addition to these primary selective markers, there are also secondary markers that are unsuitable for direct selection when only a few plastid DNA copies are transformed but that are able to confer a selective advantage when most genome copies are transformed (Maliga, 2004). Examples are the bacterial *bar* gene that detoxifies the herbicide phosphinothricin (Lutz et al., 2001) and the *CP4* gene that confers resistance to the herbicide glyphosate (Ye et al., 2003). Due to the limited repertoire of marker genes available for plastid transformation, it would be highly desirable to increase the range of selective marker systems. One of the major obstacles to extending this chloroplast-based technology to major important crops is the lack of suitable selective markers (Daniell et al., 2002). Some species are naturally resistant to antibiotics used in plastid transformation (e.g., maize and rice are spectinomycin-resistant) (Fromm et al., 1987). In other species such as cotton, transplastomic plants were not recovered after bombardment and spectinomycin selection, even at low concentrations. However, plastid transformation was achieved under kanamycin selection (Kumar et al., 2004). Therefore, a wider variety of selective marker systems would ease the transformation of recalcitrant species. Whereas protein synthesis begins with methionine in the cytosol, the process of translational initiation of proteins in plastids and mitochondria is similar to that of eubacteria, resulting in the incorporation of formyl-methionine at the N-terminus. The formyl group is later excised from the nascent polypeptide by a peptide deformylase (PDF). Deformylation is an essential process both in prokaryotes and eukaryotes, despite proteomics analysis have also revealed a number of cases in which plastid-encoded proteins retain the formyl group (Giglione and Meinnel, 2001). *PDF* mutants in *E. coli* are lethal (Mazel et al., 1994; Meinnel and Blanquet, 1994), resulting in an albino phenotype in *Arabidopsis thaliana* (Giglione et al., 2003) and display chlorosis and

growth retardation in rice (Moon et al., 2008). Moreover, excision of the formyl group is a necessary step for the subsequent removal of the initial methionine by a methionine aminopeptidase in proteins that do not retain this amino acid at the N-terminus in their mature forms. These post-translational modifications contribute to the turnover of the formate and methionine compounds in the stroma of plastids.

Actinonin, a pseudo-peptide hydroxamate derivative, is a selective and potent inhibitor of bacterial deformylases (Chen et al., 2000). Plant deformylases are also very sensitive to actinonin (Giglione and Meinel, 2001). The effects of actinonin treatment in plants include the inhibition of seed germination, an induced albino phenotype in germinated seedlings, chlorosis and a severe reduction in plant growth (Dirk et al., 2001; Giglione et al., 2003; Serero et al., 2001). The inhibition of peptide deformylase resulted in decreased D1 protein accumulation in tobacco chloroplasts, probably due to incorrect cotranslational processing, leading to photosystem II disassembly and leaf necrosis (Hou et al., 2004). Therefore, actinonin and other functional homologues have been proposed as a new class of broad-spectrum herbicides (Hou et al., 2006).

Two peptide deformylase genes have been identified in *Arabidopsis thaliana* (Dirk et al., 2001; Giglione et al., 2000) and three in rice (Moon et al., 2008). *Arabidopsis* deformylase genes have been extensively studied, and subcellular localization experiments show that *AtPDF1A* and *AtPDF1B* are present in mitochondria and chloroplasts (Hou et al., 2007; Moon et al., 2008). Due to the low similarity between *AtPDF1B* and the *E. coli* deformylase (Dirk et al., 2001), it is conceivable that a compound without antibacterial activity that specifically inhibits plant PDF1B could be developed. In this context, *AtPDF1B* would be an ideal selective marker for plant transformation that would eliminate the use of marker genes conferring antibiotic-resistance, avoiding the biosafety concerns about the use of such genes derived from micro-organisms (Miki and McHugh, 2004). With this objective, transgenic nuclear tobacco plants expressing different forms of *Arabidopsis* PDF were evaluated for resistance to actinonin (Hou et al., 2007). The over-expression of *AtPDF1A.2* or *AtPDF1B* resulted in resistance to actinonin, suggesting that the combination of plant PDF and actinonin could serve as a native gene selective marker system for plant transformation vectors.

In the present work, we expressed the *AtPDF1B* gene in tobacco chloroplasts and analysed the resistance of the transplastomic plants to actinonin. The aim of this study was to evaluate the potential of plant deformylases as new selective marker genes for plastid transformation.

Materials and methods

Construction of the chloroplast expression vector

The peptide deformylase *PDF1B* cDNA (clone RAFL07-10-E08) from *Arabidopsis thaliana* was obtained from the Riken *Arabidopsis* Full-Length Clone Database (www.brc.riken.go.jp/lab/epd/Eng/). For cloning into the chloroplast expression pAF vector (Fernandez-San Millan et al. 2008), the *PDF1B* gene was amplified by PCR with the following

primers: 5'-GGTACCGGAGGCAACCATGGCCGTCTGTAAGTCTTCC-3' and 5'-CGAGCGGCCGCTTAATGGTGATGGTGATGGTGACGTTTGCCAAAACCAAC-3'. The PCR product, which included new *NcoI* and *NotI* restriction sites and the sequence corresponding to a 6x His-tag in the carboxy terminal, was cloned into the pGEM-T easy vector (Promega). *PDF1B* (840 bp) was digested with *NcoI/NotI* and fused to the promoter and 5'-untranslated region of the tobacco chloroplast *psbA* gene in a pKS intermediate vector. Finally, the fusion was digested with *EcoRV/NotI* and introduced into the pAF vector. The final pAF-*PDF1B* clone was sequenced, and its functionality was tested by western blot using *E. coli* soluble extracts.

Chloroplast transformation by particle bombardment under spectinomycin selection

Gold microprojectiles (0.6 µm) coated with pAF-*PDF1B* plasmid DNA were bombarded into tobacco (*Nicotiana tabacum* var. Petite Havana) *in vitro*-grown leaves using the biolistic device PDS1000/He (Bio-Rad) as previously described (Molina et al., 2004). After bombardment, leaves were cut into small pieces and cultured in Magenta vessels (Sigma) in RMOP medium (Murashige and Skoog mineral salts, 30 g/L sucrose, 0.1 mg/L NAA, 1 mg/L BAP, 1 mg/L thiamine, 100 mg/L myo-inositol and 6 g/L phytagar, pH 5.8) supplemented with 500 mg/L spectinomycin dihydrochloride as the selective agent. Resistant shoots were subjected to a second round of selection under the same conditions. Regenerated plants were transplanted and grown in a phytotron for further experiments.

Southern blot analysis

Total plant DNA was extracted from leaves of two-month-old plants using the cetyltrimethylammonium bromide (CTAB) procedure (Murray and Thompson, 1980). Twenty micrograms of total DNA was digested with *HindIII*, separated on a 0.8% (w/v) agarose gel and transferred to a nylon membrane. The pUC-CT vector (Lee et al., 2003), digested with *BglII* and *BamHI*, generated a 0.81 kb probe (P1) homologous to the flanking sequences. A 0.32 kb fragment (P2 probe) of the *PDF1B* gene was obtained by *SmaI-NotI* digestion of the pAF-*PDF1B* vector. Hybridisation was performed using the chemiluminiscent AlkPhos direct labelling-detection system (GE Healthcare). After Southern blot confirmation, plants were transferred to soil. Seeds from the T₀ generation were *in vitro* germinated on spectinomycin selection medium. The T₁ seedlings were isolated and cultured for four weeks in Magenta vessels. Finally, plants were transferred to pots.

Purification of recombinant PDF1B from transplastomic plants

Soluble *PDF1B* was affinity-purified using Ni-NTA Agarose (Qiagen) according to the manufacturer's protocol and buffers. Briefly, 5 g of leaves was ground in liquid nitrogen and mixed with sonication buffer (50 mM NaH₂PO₄, 300 mM NaCl and 10 mM Imidazole, pH 8). After 5 min of sonication and 15 min of centrifugation at 20,000 **g**, the supernatants were filtered through two layers of miracloth. Filtrates were mixed with 500 µL of Ni-NTA agarose, incubated in a rotary shaker for 90 min at 4°C and passed through a gravity-flow chromatography column

to separate the agarose with affinity-attached proteins from the debris. The column was washed with 20 mL of washing buffer (50 mM NaH₂PO₄, 300 mM NaCl and 20 mM Imidazole, pH 8), and proteins were eluted in 8 mL of elution buffer (50 mM NaH₂PO₄, 300 mM NaCl and 250 mM Imidazole, pH 8). The eluates were concentrated and dialysed against 50 mM Hepes and 10 mM ClNa at pH 7 in a Vivaspin 10 MWCO PES concentrator (Sartorius). Proteins were quantified by a Bradford assay (Bio-Rad). Purified samples were stored at 4°C until the activity assays were performed.

Western blot analysis and PDF quantification

Leaf discs (100 mg) were ground in liquid nitrogen and homogenised in phosphate-buffered saline (PBS) at pH 7.4. After centrifugation at 20,000 *g* for 5 min, the supernatant was the soluble fraction. The pellet was resuspended in 200 µL of loading buffer (250 mM Tris-HCl, pH 6.8, 4% SDS, 10% glycerol, 10% β-mercaptoethanol and 0.01% bromophenol blue) and boiled for 5 min. After centrifugation at 20,000 *g* for 5 min, the supernatant was considered the insoluble fraction. For *E. coli* expressing PDF1B from the pAF-PDF1B vector, 3 mL of an overnight culture was pelleted, resuspended in 100 µL of loading buffer and boiled for 5 min.

Proteins were separated on 12% SDS (w/v) polyacrylamide gels and transferred onto nitrocellulose membranes (Hybond C, GE Healthcare), blocked overnight in PBS with 0.1% (v/v) Tween-20 (PBS-T) and 5% skim milk (PBS-TM) and incubated for 1 h with HRP-conjugated anti-His antibody (Sigma) diluted 1:20 000 in PBS-TM. After two washes of 10 min in PBS-T, the specific signal was detected using the Advanced ECL system (GE Healthcare) according to the manufacturer's instructions. Affinity-purified PDF1B, as described previously, was used as the standard in the range of 100-600 ng. Transgenic leaf extracts were diluted to fit within the linear range of the standards and measured by densitometry with the GeneTools analyser (Syngene).

Peptide deformylase fluorescence assay

The deformylase activity was measured in a fluorescent assay using fluorescamine to monitor the release of formate from a N-formylated peptide substrate and to detect the formation of the new amino group (Haas et al., 2001). Fluorescamine reacts directly with primary amines to yield highly fluorescent fluorophors. The substrate for deformylation was formyl-Met-Ala-Ser (fMAS, Bachem, Germany). The deformylase activity was measured in 96-well microtitre plates. Different dilutions (150-1200 nM) of the affinity-purified enzyme and variable concentrations (0-10 mM) of the peptide fMAS were incubated for 40 min at room temperature in a 50 µL reaction volume (50 mM HEPES and 10 mM NaCl, pH 7.3). After the addition of 20 µL of a fluorescamine (Sigma) solution (0.2 µg/mL in 100% DMSO), the fluorescence was determined using a fluorescence plate reader (Multiskan Ex, Labsystems) with the excitation wavelength at 390 nm and the emission wavelength at 485 nm. The results were expressed as relative fluorescence units (RFU).

Antibiotic susceptibility tests

Actinonin inhibitory effect on deformylation activity

Affinity-purified PDF1B (1200 nM) from transplastomic tobacco plants was pre-incubated for 15 min with 0-1000 nM actinonin prior to initiating the reaction by adding 7.5 mM fMAS. After a 40 min incubation at room temperature, 20 μ L of fluorescamine solution was added, and the fluorescence was measured as explained above.

Germination of tobacco seeds with actinonin

Tobacco seeds from two transplastomic lines were germinated in the wells of 96-well microtitre plates containing Murashige and Skoog mineral salts including vitamins (Duchefa), 30 g/L sucrose, pH 5.8, and 0.6% microagar (Duchefa) in the absence or presence of different levels of actinonin (300-600-1200 μ M). As control, seeds were also germinated on medium containing 500 mg/L spectinomycin. Plates were incubated for 30 days in the culture chamber, and seedling development was recorded.

Actinonin treatment of leaves

Mature leaves of transgenic and wild-type plants grown in a phytotron were treated daily with 5 μ L of 0.1, 5 or 10 mM actinonin in 0.05% (v/v) Tween-20 for six days. Drops were placed every day with a pipette tip on the same point of the adaxial side of the leaves. Three replicates on two different plants were performed.

Organogenesis of transplastomic leaves in actinonin-containing media

Leaves from phytotron-grown T1 transplastomic plants were cut into 5x5 mm pieces and placed abaxial side down onto RMOP medium supplemented or not with actinonin (600-1200 μ M) or 500 mg/L of spectinomycin as the control. Twenty-four-well plates were used with 700 μ L of medium and one explant per well.

Bombardment and regeneration of chloroplast transgenic plants under actinonin selection

Bombardment with pAF-PDF1B vector was performed as described above. After bombardment, leaves were cut into small pieces (approximately 30 explants per leaf) and cultured in six-well plates containing three explants and 6 mL of RMOP medium supplemented with 0, 300, 600, 800, 1000 or 1200 μ M actinonin per well. As the control, RMOP, with or without spectinomycin dihydrochloride (500 mg/L) as the selection agent, was used. Explants were transferred to fresh medium after three to four weeks. Shoots (0.5–1 cm in length) developed after seven weeks of culture were cut and subcultured in rooting medium (Murashige and Skoog mineral salts including vitamins, 30 g/L sucrose, pH 5.8, and 0.6% microagar) supplemented with 500 mg/L spectinomycin to evaluate the transgenic nature of the regenerants. Total DNA from shoots developed under 600-1200 μ M actinonin was extracted and subjected to a PCR analysis to detect the insertion of *AtPDF1B* and *aadA* genes in the plastid genome. Control shoots developed in the presence of spectinomycin were analysed by PCR with primers 3P and 3M (Figure 1a) to detect the insertion of the *aadA* gene.

Results

Vector construction and generation of transplastomic plants

The pAF vector (Fernandez-San Millan et al., 2008) was used for tobacco chloroplast transformation. This vector includes the *trnI* and *trnA* border sequences, homologous to the inverted repeat regions of the tobacco plastid genome, and the aminoglycoside 3'-adenylyltransferase (*aadA*) gene from *E. coli*, which confers resistance to spectinomycin. Border sequences mediate the integration of the foreign DNA into the plastid genome by homologous recombination. The *Arabidopsis thaliana* *PDF1B* cDNA was inserted in the pAF vector under the control of the promoter and 5'-untranslated region of the *psbA* gene, yielding the final pAF-PDF1B vector (Figure 1a). The PDF1B recombinant protein included the original transit peptide sequence and a carboxy terminal 6xHis-tag. Previously, it was shown that a C-terminal His-tag fusion did not affect PDF enzymatic activity (Dirk et al., 2001). We selected *PDF1B* instead of *PDF1A* because of the higher actinonin tolerance of PDF1A in *in vitro* assays (Dirk et al., 2001) and in nuclear transgenic tobacco plants over-expressing either *PDF1B* or *PDF1A* (Hou et al., 2007).

Chloroplast transformation was performed by particle bombardment following previously described protocols (Molina et al., 2004). Bombarded leaf fragments were cultured under the selection of spectinomycin to obtain transformed shoots.

Determination of chloroplast integration and homoplasmy

Plantlets that developed after the transformation process were analysed for transgene integration in the plastid genome by PCR with primers 3P and 3M. Primer 3P binds on the plastid genome upstream of the *trnI* gene outside the vector integration site, and primer 3M binds to the *aadA* gene (Figure 1a). The resulting PCR product (1.65 kb) is specific for transformed plastid genomes and cannot be amplified from nuclear transgenic plants. Ten independent plantlets were analysed, and all of them were PCR-positive, whereas wild-type samples did not amplify any fragment (data not shown). Subsequently, a Southern blot analysis of five plants was performed to confirm site-specific integration and to verify homoplasmy. Total plant DNA was digested with *HindIII*. DNA from non-transformed plants produced a fragment of 7.8 kb when it was hybridised with the flanking-region probe (P1, Figure 1b,c). Transformed plants produced a fragment of 10.1 kb. All five independent plants analysed were homoplasmic, showing the fragment of 10.1 kb but lacking the signal of 7.8 kb corresponding to the wild-type plastid genome (Figure 1c). To confirm that the 10.1 kb fragment contained the *PDF1B* sequence, the same blot was re-probed with the P2 probe (Figure 1b). As expected, hybridisation was observed in the five transgenic lines but was absent in the non-transformed plant (Figure 1d). Seed germination and green plantlet development on spectinomycin-containing medium confirmed that homoplasmy was maintained in the T₁ generation of both transplastomic lines (data not shown).

Expression and quantification of the PDF1B protein

The *Arabidopsis thaliana* PDF1B protein expressed in transgenic chloroplasts was detected by western blot with an anti-histidine antibody. A 25-kDa band of the expected size for the mature PDF1B was detected (Figure 2a)(Dirk et al., 2001). The recombinant protein included its original N-terminal transit peptide sequence of 56 residues that presumably would be cleaved in the chloroplast by a general stromal processing peptidase after the synthesis of the polypeptide. To confirm this point, protein extracts from *E. coli* transformed with pAF-PDF1B were subjected to western blot. As expected, a band of higher molecular mass was detected (Figure 2a), denoting non-processing of the signal peptide in *E. coli* (Dirk et al., 2001) and confirming its removal when PDF1B was synthesised in the chloroplast. The enzymatic machinery of the plastid is able to process transit peptides of recombinant proteins expressed in the chloroplast. For example, cleavage of the transit peptide from the Rubisco small subunit fused to the human serum albumin expressed in tobacco chloroplasts was previously demonstrated (Fernandez-San Millan et al., 2007).

The foreign protein was mainly detected in the soluble fraction as a single band (Figure 2b), suggesting the absence of insoluble aggregates of multimeric structures, frequently present when high expression levels are achieved in the chloroplast (Fernández-San Millán et al., 2003; Fernandez-San Millan et al., 2008). This point was confirmed when protein samples were run under native conditions, and only the monomeric band was detected (data not shown). The effect of leaf age on PDF1B protein expression was analysed in plants grown in the greenhouse for 60 days. Young, mature and old leaves (12, 8 and 3 leaves, respectively, counted from the bottom of the plant) were selected. Strong bands were observed in young and mature leaves, but the signal was very weak in old leaves (Figure 2b). Lack of accumulation of PDF1B in old leaves could indicate a high sensitivity of this protein to chloroplast proteases, though no degradation products were detected in the western blot. As previously shown, unstable foreign proteins expressed in chloroplasts show a decline in protein accumulation with leaf age (Farran et al., 2008).

The amount of PDF1B accumulated in the chloroplast was quantified by western blot using affinity-purified PDF1B as the standard. Different amounts of protein extracts were loaded onto the gel. After developing the film, the blot was analysed by densitometry (Figure 2c). The mean value of three independent experiments was calculated, and the expression level of the foreign protein was estimated as 0.61 mg/g fresh weight of leaf (equivalent to 6% of the total soluble protein). To confirm this data, total protein extracts from transplastomic and wild-type plants were separated by SDS-PAGE and stained with Coomassie brilliant blue. A 25-kDa band corresponding to the PDF1B protein was visualised in the transplastomic plant but was absent in the non-transformed plant (Figure 2d). Transplastomic plants showed some phenotypic differences such as the light green colour of leaves in comparison to wild-type plants (data not shown). Additionally, lower Rubisco levels were detected in these plants (Figure 2d). However, plants developed normally and set seeds.

Chloroplast-produced PDF1B catalyses peptide deformylation

The affinity-purified recombinant PDF1B catalysed the deformylation of the fMAS peptide, a common substrate used in enzymatic deformylase assays (Haas et al., 2001). As expected, fluorescence increased with higher concentrations of the peptide substrate (Figure 3a). In addition, an increase in relative fluorescence units was detected with increasing levels of deformylase.

Actinonin is a naturally occurring inhibitor of bacterial peptide deformylase. It was previously shown that actinonin inhibited the enzyme activity of *Arabidopsis thaliana* PDF1B (Dirk et al., 2001). We found that actinonin also inhibited the chloroplast-produced PDF1B (Figure 3b). Over 80% inhibition of the enzymatic activity was observed with 10 nM actinonin.

Over-expression of PDF1B in the chloroplast confers resistance to the peptide deformylase inhibitor actinonin

Seeds from two independent transplastomic lines were *in vitro* germinated in the presence of different concentrations of actinonin. Wild-type seedlings showed small and bleached cotyledons and growth arrest even at the lowest level of actinonin, similar to the effect observed with spectinomycin (Figure 4a). In contrast, transplastomic plantlets developed green cotyledons and true leaves. A slight growth delay was observed in plant development, especially at the highest concentration of actinonin (1200 μ M). Transplastomic PDF1B plants were transplanted, displaying a normal fertility. *In planta* experiments also demonstrated that transplastomic plants were actinonin-resistant. Six days after leaf treatment with actinonin droplets, bleached spots were observed in wild-type leaves, but transformed leaves were unaffected irrespective of the actinonin concentration (Figure 4c). The sensitivity of tobacco plants to actinonin was previously demonstrated *in vitro* (Hou et al., 2007) and *in vivo* (Hou et al., 2004).

To assess the organogenic capacity of the transformed plants, leaf explants were cultured on RMOP medium supplemented with actinonin. Thirty days after culture with 600 μ M of actinonin, leaf explants expanded and developed buds in a similar way to the control without actinonin or the medium including spectinomycin (Figure 4b). Buds were also produced with 1200 μ M of actinonin, though the explant growth was reduced. Organogenesis on non-transformed leaf explants was totally inhibited by 1200 μ M of actinonin. Under these conditions, growth was also arrested, and explants bleached and died (Figure 4b). At 600 μ M of actinonin, despite a growth delay, some buds developed. These results suggest that actinonin should be used as selective agent at concentrations higher than 600 μ M to completely avoid the development of non-transformed shoots.

PDF1B is not an appropriate selective marker for chloroplast transformation

After confirming that *AtPDF1B* could be expressed in the stroma of the chloroplast, was enzymatically active and conferred resistance to actinonin, we wanted to test whether the

combination of the *PDF1B* gene with a PDF inhibitor could serve as a selective marker system for chloroplast transformation. The pAF-PDF1B vector, described above, was used for particle bombardment of *in vitro*-grown leaves. Bombarded leaf explants were grown under different concentrations of actinonin, instead of the antibiotic spectinomycin that was used in the first transformation experiment. Here, spectinomycin was employed as the control selective marker. Fifty days after bombardment, green shoots had developed under all levels of actinonin treatment, with the exception of 1200 μ M, where the initial explants turned brown (Figure 5a). The 29 shoots developed under the control of spectinomycin selection were analysed at the molecular level. PCR analysis with primers that bind on the *trnI* and *aadA* genes (Molina et al., 2004) confirmed that 100% of the shoots were transformants rather than spontaneous spectinomycin resistant mutants (data not shown). All shoots (182) developed in the presence of actinonin were excised and transferred to a rooting medium including spectinomycin. If the transgenes had inserted in the plastid genome, developed shoots should be spectinomycin-resistant. However, all shoots bleached, suggesting that they were escapes developed in the presence of actinonin. Another explanation could be that, under low actinonin selective pressure, few copies of the transformed plastid genome were present relative to the wild-type plastid genome, facilitating the development of non-transformed spectinomycin-sensitive shoots. To analyse the presence of the transgenes, total DNA from shoots developed under 600-1200 μ M actinonin treatment was extracted and subjected to a PCR analysis with primers specific for *AtPDF1B* and *aadA*. No amplification of fragments of the expected sizes was observed (data not shown). A new experiment with an increased number of bombardments (12/concentration of actinonin) was performed and selection carried out through the higher levels analysed (800, 1000 and 1200 μ M) (Figure 5c). Again, organogenesis was not observed in the highest concentration of actinonin, and all shoots (118) developed in the media containing 800 or 1000 μ M of the PDF inhibitor bleached when transferred to a rooting medium including spectinomycin. PCR analysis of DNA from these shoots to detect the presence of *AtPDF1B* and *aadA* were also negative (data not shown). The 23 shoots developed under the control spectinomycin selection were analysed by PCR and 22 of them resulted to be true transformants and one was a spontaneous spectinomycin resistant mutant (data not shown).

Discussion

Actinonin has a phytotoxic effect in crop plants (Giglione et al., 2003; Moon et al., 2008; Serero et al., 2001) and in weed species (Hou et al., 2006). This compound specifically inhibits PDF, a metallopeptidase that catalyses the removal of the formyl group from formyl-methionine, the initial amino acid for all proteins synthesised in the plastids. Over-expression of *PDF1B* by nuclear transformation conferred protection to actinonin, suggesting the potential use of this system as a new selective marker (Hou et al., 2007). To test this hypothesis, transgenic tobacco plants expressing the *Arabidopsis thaliana* *PDF1B* in their chloroplasts were developed in this study, and high expression levels of the foreign protein were achieved. The recombinant protein

was also visualised by PAGE and Coomassie brilliant blue staining. The over-expression of the PDF1B protein in the stroma of the chloroplast made the transplastomic plants resistant to actinonin. However, in our hands, the combination of *AtPDF1B* and actinonin as the primary selective marker system did not allow the recovery of transplastomic tobacco plants. Therefore, the use of this system would be limited to function as secondary selective marker, equivalent to *bar* and *CP4* genes (Lutz et al., 2001; Ye et al., 2003).

In *Arabidopsis* wild-type plants, PDF1B is expressed at very low levels in the stroma of the chloroplast (Dirk et al., 2001). In our transplastomic plants, we presumably have much higher levels of deformylase than in wild-type plants and approximately 100-fold higher expression than in nuclear transgenic tobacco plants transformed with the same gene (Hou et al., 2007). As a consequence, very high levels of deformylase activity were expected. Notwithstanding this, no plastid transformants were recovered when actinonin and *AtPDF1B* were used as the primary selective system. Therefore, where does the inefficiency of this marker system lie? Several hypotheses can be formed. Firstly, the *Arabidopsis* PDF1B protein produced in the tobacco chloroplast is not properly assembled. Analysis of the crystal structure and gel filtration chromatography suggests that *AtPDF1B* exists as a dimer (Dirk et al., 2008). Our results showed that heterologous PDF1B is present in tobacco chloroplasts as a monomer, and no dimer was detected (Figure 2a,b). The dimer conformation could favour protein stability and increased enzymatic activity. Secondly, tobacco has been reported to be more resistant to actinonin compared to other species such as pea and *Arabidopsis* (Hou et al., 2004), and this could favour the development of escapes. Organogenesis in wild-type explants was completely inhibited at the highest concentration of actinonin (1200 μ M) but not at lower levels (Figure 4b), where shoots developed. Under these circumstances, it would be normal in a transformation experiment to observe the development of non-transformed plants under low selective pressure. Thirdly, because the *in vitro* transformation process lasts several weeks, it is conceivable that selective pressure decreases with time, allowing the formation of buds from non-transformed cells. It has been demonstrated that actinonin is rapidly metabolised and inactivated after absorption, with only 17% of the original compound remaining 48 h after *in vivo* application (Hou et al., 2006). However, the observed results indicate that some active actinonin was present during the whole period of *in vitro* culture. Lower numbers of shoots and growth delay were noticed compared to actinonin-free medium at the end of the culture period (Figure 5), suggesting that actinonin stability is not a key issue in this study.

In conclusion, though *Arabidopsis* PDF1B can be expressed at high levels in tobacco chloroplasts without deleterious effects on plant growth and development, and the recombinant protein conserves its enzymatic activity, the combination of actinonin and PDF does not yield a suitable primary selective marker system for plastid transformation.

Figure legends

Figure 1. Schematic representation of plastid genome transformation with the *Arabidopsis thaliana* *PDF1B* gene (constructs not drawn to scale). **(a)** Map of the wild-type and *PDF1B*-transformed genomes. Regions for homologous recombination are underlined in the native chloroplast genome. The *PDF1B* sequence is driven by the *psbA* promoter. The annealing sites of the primers (3P and 3M) used to test integration of the cassette into the chloroplast genome are shown. **(b)** The 0.8-kb fragment (P1) of the targeting region for homologous recombination and the 0.32-kb *PDF1B* sequence (P2) were used as probes for a Southern blot analysis. **(c, d)** The Southern blot analysis of five independent transgenic lines (1-5) is shown. The same blot was probed with P1 (c) and P2 (d). *16S*, *23S*, *trnI*, *trnA*: original sequences of the chloroplast genome; *aadA*: aminoglycoside 3'-adenylyltransferase; *Prrn*: 16S rRNA promoter; *PpsbA*: *psbA* promoter and 5'-untranslated region; 3'*psbA*: terminator region of the *psbA* gene; WT: wild-type; M: molecular weight marker.

Figure 2. Characterization of *PDF1B* expression in transgenic chloroplasts. **(a)** Immunoblot analysis of transit peptide processing in tobacco chloroplasts. Extracts from *E. coli* transformants and from *E. coli* transformed with the empty vector (C) were loaded as controls. **(b)** Soluble and insoluble proteins extracted from 1.5 mg of leaf fresh weight per well were

loaded on a 12% SDS-PAGE. Young (Y), mature (M) and old (O) leaves were analysed. Total protein extract from wild-type (WT) leaf was loaded as the control. Blots were detected using anti-His HRP conjugated antibody. **(c)** PDF1B quantification in transgenic tobacco chloroplasts by western blot analysis. Total protein extracts from 1.2, 0.6 and 0.3 mg of leaves were loaded for quantification. As standards, 100-600 ng of purified PDF1B protein were used. **(d)** Coomassie-blue stained SDS-PAGE gel. Fifteen micrograms of total protein extracted from transplastomic (T) or wild-type (WT) plants was loaded.

Figure 3. Activity of chloroplast-expressed PDF1B. **(a)** Effects of increasing concentrations of fMAS peptide addition on variable amounts of purified PDF1B: 150 nM, 300 nM, 600 nM and 1200 nM. Control: wild-type protein extract purified in parallel to PDF1B. RFU: Relative fluorescence units. **(b)** Dose-response relationship of actinonin inhibition against PDF1B. The deformylation activity of 1200 nM PDF1B was measured in the presence of 7.5 mM fMAS and increasing concentrations of actinonin. The error bars represent the standard errors of the data from three independent experiments.

Figure 4. Tolerance of transplastomic plants to the peptide deformylase inhibitor actinonin. **(a)** Seeds from two transplastomic lines (T1 and T2) and wild-type plants (WT) were germinated on medium containing 0, 300, 600 or 1200 mM actinonin or 500 mg/l of spectinomycin. Seedlings were grown for 30 days. **(b)** Organogenesis of leaf explants from transplastomic (T) or wild-type (WT) plants on RMOP medium supplemented with 0, 600 or 1200 mM of actinonin after 30 days. Spectinomycin was used as the positive control. **(c)** Effect of actinonin (six-day treatment with 5 ml of solution) in leaves of transplastomic (T) or wild-type (WT) plants grown in a phytotron (bar represents 1 cm).

Figure 5. Chloroplast transformation experiment with actinonin as the selective marker. **(a)** Shoot regeneration on leaf explants cultured on RMOP medium containing 0, 300, 600, 800, 1000 or 1200 mM actinonin, or 500 mg/l of spectinomycin as the control, 50 days after bombardment with the pAF-PDF1B vector (bar represents 1 cm). **(b, c)** Number of bombarded leaves, selected leaf pieces, regenerated shoots and resistant plantlets after transferring the shoots to a rooting media supplemented with 500 mg/L spectinomycin. Spec: spectinomycin.
