FLUORESCENCE STUDY OF THE PROOXIDANT ACTIVITY OF FREE FATTY ACIDS ON MARINE LIPIDS

ABSTRACT

The free fatty acids (FFA) effect on the oxidative stability of marine lipids was studied by fluorescence assessment. Under different reaction conditions including time, temperature, FFA content and types (different chain length and unsaturation degree), FFA were made to interact in model systems with a commercial marine oil (cod liver oil) and two different fish (hake and pout) white muscles. Fluorescence assessment showed a prooxidant effect of all kinds of FFA, that increased with time, temperature and FFA content in the reaction mixtures. At 30°C, a higher degree of oxidation was obtained in systems including the shorter chain length fatty acids (lauric and myristic) compared to systems including the longest ones (arachidic and stearic); at the same temperature, an increasing prooxidant effect was also observed with increasing degree of the fatty acid unsaturation (stearic < oleic < linoleic < linolenic). When a lower temperature (-10°C) was tested, a differential prooxidant effect among fatty acids (chain length and unsaturation degree) was not observed.

Running Title: Prooxidant activity of free fatty acids

Keywords: Marine lipids, oxidation, free fatty acids, chain length, unsaturation degree, fluorescence assessment

INTRODUCTION

During fish processing and storage, quality may decline as a result of several factors. One of the most important concerns the lipid oxidation damage (1,2) because of the highly unsaturated composition of marine fatty acids (3) and the great diversity and content of different prooxidant molecules present in the fish muscle (4,5). As a result, the degree of lipid deterioration during technological transformation of fish has been found to be closely related to the final product quality and shelf life (6,7).

Enzymatic and non-enzymatic lipid hydrolysis was shown to occur during fish processing (8-10). Formation of free fatty acids (FFA) itself does not lead to nutritional losses. However, accumulation of FFA has been related in some extent with lack of acceptability, because FFA are known to cause detrimental effect on ATPase activity, protein solubility and relative viscosity (11), texture deterioration by interacting with proteins (12) and to be interrelated with lipid oxidation development (13).

It has been found that FFA originated from both polar and neutral lipids, although some differences have been found in the literature about the relative importance of both lipid groups depending on the process, species and temperature tested (14,15). The FFA content has successfully been employed to assess fish deterioration during frozen storage (16), chilled storage (17) and ripening of anchovies (18).

Previous research based on traditional lipid oxidation indices has proved a lower oxidative stability in FFA than in their corresponding methyl esters and triglycerides (19,20) and a prooxidant effect of FFA on commercial vegetable oils (21). In the present work, a rapid and accurate fluorescence assessment (22,23) was applied to determine the role that FFA may play on the oxidative stability of marine lipids. The effect of

time, temperature and varying FFA contents and types (different chain length and unsaturation degree) was examined.

MATERIALS AND METHODS

Cod liver oil (CLO) was obtained from a commercial source (Bama Geve, S. A., Barcelona, Spain). Before employing it, acid value (0.9 mg KOH/g lipids), peroxide value (1.6 meq O₂/kg lipids) (24) and fatty acid composition were analysed. The following proportions (%) of the fatty acids were obtained by gas-liquid chromatography (GLC) (25): 3.55 (C 14:0), 0.46 (C 15:0), 16.22 (C 16:0), 8.12 (C 16:1 ω 7), 5.12 (C 18:0), 15.59 (C 18:1 ω 9), 4.36 (C 18:1 ω 7), 1.69 (C 18:2 ω 6), 8.36 (C 18:3 ω 3), 2.11 (C 20:1 ω 9), 0.79 (C 20:4 ω 6), 8.07 (C 22:1 ω 11), 0.73 (C 20:4 ω 3), 11.63 (C 20:5 ω 3), 0.41 (C 24:0), 0.54 (C 22:4 ω 6), 1.14 (C 22:5 ω 3) and 11.68 (C 22:6 ω 3).

Chemicals employed (propylamine and organic solvents) were reagent grade (E. Merck, Darmstadt, Germany). Individual fatty acids employed were GLC quality ($\geq$ 99.5 %) (Fluka, Chemie AG, Buchs, Switzerland) and their quality was checked by GLC.

Cod liver oil reaction systems

CLO reaction mixtures described bellow were incubated in all cases in triplicate in stoppered tubes in the dark at the mentioned temperature without stirring. Blank samples consisted of the individual starting reagents (CLO; propylamine, Pam; FFA), CLO + Pam and FFA + Pam mixtures under the same reaction conditions.

Propylamine was chosen as being a common and reactive amine already employed as nucleophilic compound in this kind of model systems to interact with lipid oxidation compounds produced (26,27).

Myristic acid experiments: Solutions of myristic acid (MA) (83.3 mg/250 ml chloroform; 1.46 mM) and Pam (0.987 g/500 ml aq. 86% ethanol; 33.40 mM) were prepared. The MA solution was added to CLO portions (0.5 g) to obtain the following MA/CLO (w/w) proportions: 0.01% (MA₁), 0.03% (MA₂), 0.10% (MA₃), 0.30% (MA₄), and 1.00% (MA₅); chloroform was employed to complete each reaction system to 15 ml volume. Then, 15 ml of the Pam solution were added. Samples were incubated at 30°C and analysed at day 1, 3, 7, 14 and 25; mixtures consisting in the 1.00 % proportion (MA/CLO) were also incubated at 15°C and 55°C.

Different fatty acids experiments: Chloroform solutions (1.2 mM) of each fatty acid (lauric, LA; myristic, MA; palmitic, PA; stearic, SA; arachidic, AA; oleic, OA; linoleic, LnA; linolenic, LnnA) were prepared. CLO portions (0.5 g) were mixed with 15 ml of each fatty acid solution. Then, 15 ml of the above mentioned Pam solution (33.40 mM) were added. Samples were incubated at 30°C and –10°C. Sampling was carried out at day 1, 3, 7, 14 and 25 (30°C experiment) and at month 0.5, 1, 2, 4, 6, 9 and 12 (-10°C experiment).

Fish muscle reaction systems

Fresh hake (*Merluccius merluccius*) and pout (*Trisopterus luscus*) were purchased 10 hr after catching; during this time the fish had been kept on ice. Upon

arrival in the laboratory, each fish species was divided into three batches. In each batch, the white muscle was separated out and homogenised.

Minced white muscle portions (5 g) of each batch were mixed and homogenised with 9 ml of aq. 86% ethanol. Then, 1 ml of a MA solution (2.5 g/50 ml aq. 86% ethanol) was added, so that a 1% proportion MA/fish muscle (w/w) was obtained. Samples were incubated in 30 ml stoppered tubes in the dark at 30°C without stirring and sampled at 1, 3, 7, 14 and 25 days for lipid oxidation assessment.

Lipid contents of the white muscles employed were determined by the Bligh and Dyer (28) method. Mean values (g lipids/100 g muscle) were as follows: hake (0.62) and pout (0.54).

Lipid oxidation assessment

Our previous experience on fish processing (frozen and chilled storages, cooking and canning) (22,23,29,30) showed that fluorescence detection of interaction compounds provided a rapid assessment of quality changes in fish products that could be more satisfactory in most cases than traditional lipid oxidation methods (conjugated dienes, peroxide value, carbonyls, thiobarbituric acid index and polyene index). Accordingly, the same fluorescence detection was employed in the present work.

Fluorescence measurements (Perkin-Elmer LS 3B) were made at 327/415 nm and 393/463 nm excitation/emission maxima. Relative fluorescences (RF) were calculated as $RF = F / F_{st}$, where F is the sample fluorescence at each excitation/emission maximum, and F_{st} is the fluorescence intensity of a quinine sulphate solution (1 µg/ml in 0.05 M H₂SO₄) at the corresponding wavelength. The fluorescence ratio (δF) was calculated as: $\delta F = RF_{393/463nm} / RF_{327/415nm}$.

Marine oil systems were analysed directly. Fish muscle systems were centrifuged (3000 x g for 10 minutes) and filtered. The resulting liquid part was exposed to UV light (350 nm) during 30 s to destroy any retinol present and was then analysed by fluorometry. Fluorescence was measured at room temperature (16-18°C) with a path-length quartz cuvette. Sensitive settings were: 5 (samples) and 0.5 (quinine sulphate standard solution).

Statistical analysis

Fluorescence ratio (δF) values were subjected to the ANOVA one-way method ($p < 0.05$); comparison of means after the ANOVA test were performed using a least-squares difference (LSD) method (31). Slopes comparison of δF values obtained at different temperatures was carried out according to Glantz and Slinker (32).

RESULTS

Marine oil reaction systems

Lipid oxidation compounds (e.g., peroxides and carbonyls) produced from the CLO during the present experiments interacted with propylamine to produce fluorescent compounds (26,33,34). In the absence of both kinds of compounds, no fluorescence changes were produced along the reaction time; this was the case of the individual reactant blanks (Pam, individual fatty acids and CLO) and also the mixture Pam + individual fatty acids, including different reactant ratios. Accordingly, the effect of FFA on the lipid oxidation development was evaluated by comparison with the CLO + Pam reaction system, that will be considered from now as Blank.

Effect of the free fatty acid content

Different concentrations of a free fatty acid (MA) were made to react with the mixture CLO + Pam (Table 1). For all the MA concentrations, a progressive increase with the reaction time was recorded. Although significant differences were not obtained among all the concentrations tested, an increasing fluorescence development was observed as higher MA contents were employed. Comparison with the Blank (CLO + Pam) system lead to conclude a prooxidant effect of MA when present in the 0.10-1.00% concentration range.

Effect of the reaction temperature

The effect of a free fatty acid on the oxidative damage of CLO was studied at different temperatures (15°C, 30°C and 55°C; Table 2). Fluorescence measurement showed increasing values as long as reaction temperature and time increased. In agreement with results shown in Table 1, the presence of MA (1%, w/w; MA₅) led in all cases to significantly ($p < 0.05$) higher values than the corresponding Blank system (CLO + Pam).

The fluorescence development in both reaction mixtures (Blank and MA₅) showed a good linear correlation with the reaction time at all the temperatures tested, so that correlation coefficients were higher than 0.95 in all cases. In order to compare the rates of oxidation development at the three temperatures, a statistical comparison of the regression lines slopes was carried out (32). As a result, a faster ($p < 0.05$) oxidation was obtained by temperature increase. These results corroborate the strong relationship between interaction compounds formation and temperature (35,36) and the use of the fluorescence detection (δF value) as a method of assessing lipid oxidation.

Effect of the free fatty acid type

The prooxidant effect of different FFA types was tested at two temperatures (30°C and –10°C). All FFA were tested at the same concentration in the reaction medium (0.6 mM; Materials and Methods section), so that fatty acids comparison could be made.

The chain length effect was studied by comparing different saturated fatty acids. At 30°C (Figure 1), comparison with the Blank mixture showed that the presence of fatty acids led to a significantly ($p<0.05$) higher fluorescence development after day 7 in all cases. An increasing δF value was detected in the reaction system as long as the chain length of the FFA added diminished; significantly ($p<0.05$) higher values were obtained for LA and MA than for SA and AA in the latest period of the experiment (7-25 days). The fluorescence formation was also studied at –10°C up to twelve months of reaction time (Figure 2). In this case, all FFA showed a prooxidant effect after month 2; however, no significant differences ($p<0.05$) among fatty acids were obtained during the whole experiment.

The effect of the unsaturation degree was also studied for a fatty acids series having all 18 carbon atoms. At 30°C (Figure 3), the presence of all FFA tested led to significantly ($p<0.05$) higher δF values than the Blank reaction mixture from day 7 till the end of the experiment. In cases of prolonged reaction times (7-25 days) an increasing δF value was detected in the reaction systems with increasing degree of unsaturation of the FFA added ($SA < OA < LnA < LnnA$). Comparison was also carried out at a lower temperature (–10°C; Figure 4). A prooxidant effect was observed in all fatty acids analysed after two months of reaction. However, no significant differences ($p<0.05$) were observed among the fatty acids tested along the whole experiment.

Fish muscle reaction systems

MA was made to react with minced fish (hake and pout) muscle in model systems; its prooxidant effect on the muscle lipids was assessed by comparison with blank systems consisting of minced muscle.

The presence of this free fatty acid led to progressive increases of the δF value of the system with the reaction time in both fish species (Figure 5). Significant ($p < 0.05$) differences compared to the corresponding blank muscle samples were obtained in the two latest samplings (14 and 25 days).

Fish muscle blanks also showed a progressive increase with time of the δF value (Figure 5) as a result of interaction between the nucleophilic molecules from the muscle and the lipid oxidation compounds formed (29,30).

DISCUSSION

FFA have shown a catalytic effect on lipid oxidation development when marine lipids (oil and fish muscle) were tested in model systems. This effect increased with time and temperature of the reaction mixture and with the FFA content employed. Previously, this prooxidant effect was explained on the basis of a catalytic effect of the carboxyl group on the formation of free radicals by the decomposition of hydroperoxides (19,21).

Comparison of different fatty acids showed a marked increase in the catalytic effect with shorter chain length and a reaction temperature of 30°C. This difference may be explained on the basis that the shorter the chain length, the less the positive inductive

effect of the hydrocarbon chain (37), so that the above mentioned catalytic ability of the carboxyl group would be enhanced (stronger electrophilicity of the carbonilic carbon). This positive inductive effect of the hydrocarbon chain had also been observed when comparing the ability of different kinds of amines in producing fluorescent compounds (26). At the same time, an increasing FFA chain length would lead to an increasing steric hindrance (38) on the carboxyl group so that the catalysis ability would also be diminished.

An increasing degree of unsaturation of the FFA added has led to an increasing oxidation development in the reaction systems when the reaction temperature was 30°C. An explanation could be a higher ability of the free fatty acid for the free radical formation as a result of delocalization of the radical formed through the double bonds system. A higher content on free radicals would lead to a higher lipid oxidation catalysis of the lipid matter present in the system (marine oil and fish muscle) and accordingly, a higher δF value.

Reaction temperature showed to be important if differences in the prooxidant effect of different kinds of fatty acids were to be observed. At the lowest temperature tested (-10°C) decomposition rate of hydroperoxides is lower than at 30°C, so that a significantly ($p < 0.05$) different catalytic effect of carboxyl groups from fatty acids with different chain length and unsaturation degree was not obtained.

Previous research related to the influence of FFA on fish damage was focused on lean fish proteins during frozen storage. A decrease in the solubility or extractability of the protein was observed when lower molecular weight fatty acids or polyunsaturated fatty acids were present (39,40). In this case, the mechanism of interaction was thought to be through secondary forces (electrostatic, van der Waals, hydrogen forces) rather than through covalent bond formation. FFA would create more hydrophobic regions in

the protein and thereby promote greater opportunities for the formation of aggregates through intermolecular interactions leading to detrimental textural changes in the fish product (11,12).

FFA have been reported to be widely produced during the frozen storage of lean fish species as a result of enzyme catalysis (8,10,22); during processes including high temperatures (cooking and sterilisation) a chemical hydrolysis has been detected leading to a high proportion of polyunsaturated free fatty acids (9,25). Accordingly, a great attention should be paid to the FFA content and profile produced in each technological process applied to marine species.

CLO + Pam	3.45 b	4.97 b	7.74 b	10.32 b	13.77 b
CLO + Pam + LA	4.37 d	6.39 d	10.83 d	14.77 d	19.24 d
CLO + Pam + MA	4.29 d	6.27 d	10.82 d	14.65 d	19.02 d
CLO + Pam + PA	4.16 cd	6.05 cd	10.12 cd	13.99 cd	17.93 cd
CLO + Pam + SA	3.94 c	5.60 bc	9.43 c	13.20 c	17.41 c
CLO + Pam + AA	3.89 c	6.09 cd	9.67 c	13.64 cd	16.99 c

* Values in the same column followed by different letters are significantly different ($p < 0.05$). Initial δF value of CLO was 2.43 ± 0.19 .

** Fatty acids abbreviations: LA (lauric), MA (myristic), PA (palmitic), SA (stearic) and AA (araquidic). All FFA were employed at the same concentration (6 mM).

TABLE 5

Fluorescence ratio (δF) values* obtained by reaction at 30°C of cod liver oil (CLO) with propylamine (Pam) in the presence of different unsaturation degree fatty acids**

Reacting Mixture	TIME (days)				
	1	3	7	14	25
CLO	2.66 a	2.50 a	2.53 a	2.62 a	2.84 a
CLO + Pam	3.45 b	4.97 b	7.74 b	10.32 b	13.77 b
CLO + Pam + SA	3.94 c	5.60 bc	9.43 c	13.20 c	17.41 c
CLO + Pam + OA	4.04 c	6.06 cd	10.26 cd	14.65 cd	18.52 cd
CLO + Pam + LnA	4.20 c	6.75 d	11.23 de	16.09 de	21.45 de
CLO + Pam + LnnA	4.30 c	6.56 d	12.46 e	16.62 e	22.79 e

* Values in the same column followed by different letters are significantly different ($p < 0.05$). Initial δF value of CLO was 2.43 ± 0.19 .

** Fatty acids abbreviations: SA (stearic), OA (oleic), LnA (linoleic) and LnnA (linolenic). All FFA were employed at the same concentration (6 mM).

FIGURE LEGENDS

Figure 1: Fluorescence ratio (δF) values obtained in the lean fish (hake and bib) muscle systems at 30°C in the presence/absence of myristic acid (MA; 1.00 %, w/w).

* Initial fish muscle δF values: 0.78 ± 0.06 (hake) and 0.98 ± 0.10 (bib).

Figure 2: Fluorescence ratio (δF) values obtained in the fatty fish (horse mackerel, *Hmac*; sardine, *Sard*) muscle systems at 30°C in the presence/absence of myristic acid (MA; 1%, w/w).

* Initial fish muscle δF values: 0.89 ± 0.06 (horse mackerel) and 0.79 ± 0.05 (sardine).
