Abstract Summer water stress is the main limiting factor for *Pinus pinaster* growth under Mediterranean climate, but no information on limiting physiographic and climatic factors under Atlantic conditions is available for this species. We hypothesize that water availability during the active period limits *P. pinaster* growth, with stands nearby the Atlantic-Mediterranean boundary being more sensitive to summer drought stress. We analyzed the inter- and intra-annual climatic response of this species at ten monospecific stands in a transitional area between the Atlantic and Mediterranean biogeographical regions in NW Spain. Mean sensitivity of radial growth consistently decreased with increasing elevation, and growth variation was quite similar for the earlywood, latewood or total ring widths, suggesting a strong intra-annual coherency of radial growth. Growth patterns were site-dependent and geographically structured, with three groups of stands showing different climatic responses. As expected for sites suffering from summer drought stress, water availability enhances growth in western and southern Galicia, showing negative responses to maximum temperatures and positive to water availability. In northern Galicia, away from the Atlantic-Mediterranean boundary, water surplus in the rainy seasons negatively influenced growth. This was probably due to the combined effects of seasonal water-logging stress and the reduction of solar radiation associated to cloudiness, which would limit photosynthetic rates in winter and spring. Local variations of water availability strongly controlled the physiological processes that determine growth dynamics of *P. pinaster* in NW Spain, contributing to its geographical structure and contrasting sensitivity.

47 **Introduction**

48 Within the geographical range of a tree species, environmental features vary along
49 physiographic and ecological gradients at different scales, creating heterogeneity in the
50 spatial distribution of limiting factors for the species performance (Dittmar et al. 2003;
51 Fekedulegn et al. 2003). Variation in growth patterns among tree populations reflect
52 ecological and climatic variation within a given region, and can be used to detect main
53 limiting factors and geographical gradients for tree growth and forest productivity
54 (Mäkinen et al. 2002). Knowledge of the main climatic factors limiting tree growth is
55 not only vital for estimating forest productivity in a particular region, but can also be
56 very helpful to anticipate future patterns of wood productivity under changing climatic
57 conditions (Case and Peterson 2005). This is particularly true near the boundaries
58 between biogeographical regions, where limiting conditions can differentially affect the
59 growth of species with distinct origin.

60 Dendrochronological methods are appropriate to describe tree-growth patterns on
61 an annual basis and their dependence on physiographic and climatic factors at multiple
62 spatial scales (Cook et al. 2001). Detailed studies of tree-ring networks at regional and
63 stand scales are becoming more used to detect geographical patterns of tree responses to
64 limiting environmental factors (Bogino and Bravo 2008; Mäkinen et al. 2002), but most
65 of them focused on the inter-annual growth variation, which integrates the effects of
66 weather conditions operating at multiple time scales along the entire growing season
67 and preceding periods (Fritts 2001). However, the anatomical distinction between early-
68 and latewood is prominent in many tree species, and can lead to a higher temporal
69 resolution and thus provide a better understanding of the mechanisms responsible for
70 seasonal cambial activity and intra-annual growth dynamics (Lebourgeois 2000;

Zweifel et al. 2006). But detailed studies on the climatic sensitivity of intra-annual growth chronologies are generally focused on environmental gradients, or on comparing growth sensitivity in contrasted environmental conditions (Parker et al 2001; Splechna et al. 2000; Watson and Luckman 2002).

Near the limit between the Atlantic and Mediterranean biogeographical regions in NW Spain, climate is characterized by an abundant annual rainfall, but a strong seasonality of precipitation causes a water deficit during summer, especially in those areas with more Mediterranean influence (Martínez Cortizas et al. 1994). However, the climatic sensitivity of radial growth for Mediterranean tree populations near the species range boundary, where climatic and ecological limiting conditions may substantially differ from those in the range core, has seldom been assessed. *Pinus pinaster* is a native tree species from the west-Mediterranean basin, i.e. the Italian and Iberian peninsulas, southern France, Corsica, Sardinia and northern Africa (Alía et al. 1997). Its distribution range is strongly fragmented, and the isolated populations typically show strong adaptations to local environmental conditions. Water stress and cold hardiness are probably some of the main factors driving population divergence (Chambel et al. 2007).

Within the Iberian range, *P. pinaster* lives on a wide variety of soil types, physiographic and climatic conditions. Thus, it grows under warmer and drier Mediterranean conditions at altitudes up to 2,000 m in central, east and southern Spain, where summer water stress constitutes the main limiting factor (Bogino and Bravo 2008). In contrast, it only spreads up to 900 m towards the north-western Atlantic coast under a colder and moister climate (Alía et al. 1997). Results from different palaeobotanical and genetic studies suggest that *P. pinaster* spread northwards from glacial refuges in southeastern Iberia and the Atlantic coast of Portugal since 7,500–6,500 yr BP (Bucci et al. 2007; Figueiral 1995). In Galicia, NW Spain, it has been

extensively cultivated since the 19th century for productive purposes, but no formal studies have explored which the main climatic factors limiting *P. pinaster* growth under Atlantic conditions are. The pronounced genetic and physiological differences between Atlantic and Mediterranean populations (Alía et al. 1997; Bucci et al. 2007; Correia et al. 2008) suggest that the main limiting climatic factors may differ in these two regions.

In this work we analyze tree-ring growth of *P. pinaster* in Galicia, NW Spain, at inter- and intra-annual time scales, near the transition between the Atlantic and Mediterranean biogeographical regions, as defined on the basis of botanical and climatic criteria (Rivas Martínez and Loidi Arregui 1999). Based on previous evidences (Rozas et al. 2009), we hypothesize that water availability during the active period limits growth in our study area, and that stands nearby the Atlantic-Mediterranean boundary are more sensitive to summer drought stress. In order to test this hypothesis, we aim at responding the following questions: (1) How do inter-annual growth patterns of *P. pinaster* vary along its range in Galicia, NW Spain? (2) What are the main limiting climatic factors for radial growth throughout the region, and specifically under Atlantic climate and near the transition to a Mediterranean climate?

Materials and methods

Study area

The study area comprises the region of Galicia, NW Spain, at the NW range boundary of *Pinus pinaster* (Fig. 1A), where this species covers over 47% of the forest area in pure or mixed stand, and represents one of the most important commercial woods. It has been extensively planted for the last century, and the resulting even-aged stands are typically managed through rotations of 40–50 years.

Regional climate is rather heterogeneous as a result of the interaction between the prevalence of Atlantic winds and an irregular orography (Martínez Cortizas et al. 1994). Thus, the coastal area has a strong oceanic influence, with a high annual precipitation (1,500–2,500 mm), a mean annual temperature ca. 10 °C, and a short annual thermal oscillation (10–11 °C). In contrast, the southern inland area shows a proper Mediterranean climate with a remarkable summer drought, a lower annual precipitation (< 1,000 mm), higher mean temperature ca. 14.5 °C, and a pronounced annual thermal oscillation (13–14 °C) with a greater continental influence (De la Mata and Zas 2010a). Though weaker, this Mediterranean influence spreads towards transitional areas, mainly during summer, affecting the whole inland and the western Atlantic coast, while keeping moist and mild conditions in the north of the region (Martínez Cortizas et al. 1994). Soils in the study area were mainly Regosols, Cambisols and Podzols, typical of humid conditions on acidic parent materials as schist, granite and gneiss, while Luvisols, typical of climate with a marked dry season, dominate in more xeric areas (Table 1, Guitián Ojea 1974).

Sampling and tree-ring data

We sampled ten monospecific stands located both in the coastal and inland areas of Galicia along the full elevation range of *P. pinaster* in the region, from sea level to 855 m (Table 1). The stands were located in the Atlantic biogeographical region, with the unique exception of VER, within the Mediterranean region (Fig. 1B). We measured DBH (bole diameter at breast height, 1.30 m), and took at least two increment cores per tree from 15 to 24 dominant trees per stand. The cores were air dried, glued onto wooden mounts and polished with successively finer grades of sandpaper, until the xylem cellular structure was visible in the transverse plane. The tree-ring series were

absolutely dated by assigning calendar years to the rings following standard procedures (Speer 2010). Tree age was estimated based on the oldest core per tree, and no correction for the number of missing rings due to coring height was performed. Earlywood (EW) and latewood (LW) widths were measured under magnification to the nearest 0.001 mm with a sliding-stage micrometer (Velmex Inc., Bloomfield NY, USA) interfaced with a computer, and total ring (TR) widths were obtained as the sum of EW and LW on a year-by-year basis. Early- to latewood transition was defined according to a more or less gradual qualitative contrast in darkening, originated by a change in wood density. The software COFECHA (Grissino-Mayer 2001) was used to quantitatively check for crossdating errors in the ring width series. All series with potential errors or weakly correlated with the master site chronology were corrected when possible or discarded.

Climate data

We used monthly gridded data from the datasets of the Climate Research Unit (CRU), University of East Anglia, U.K., for maximum temperature (Tmax) and total precipitation (P) in the period 1967–2006, cloud-cover percentage in 1967–2002 (CRU TS 3, $0.5^\circ \times 0.5^\circ$), and for Palmer drought severity index (PDSI) in 1967–2002 (CRU self-calibrating PDSI, $0.5^\circ \times 0.5^\circ$). Data was taken from the Web site of the Royal Netherlands Meteorological Institute (<http://climexp.knmi.nl/>). The PDSI uses air temperature, cumulated rainfall and field water-holding capacity to compute a standardized measure of soil moisture ranging from –6 to 6, which corresponds to extremely dry and wet soil conditions, respectively (Dai et al. 2004). Since maximum temperature is coupled to a minimum of rainfall during summer time, precipitation data were not directly used, but incorporated to water balance estimates (WB), calculated as

WB = $P - PET$, where PET is the potential evapotranspiration estimated as a function of monthly mean temperatures and geographical latitude (Thornthwaite 1948). Mean monthly WB ranged between -75 mm in July and 145 mm in December-January, showing a tendency to water deficit from June to August.

The monthly climatic variables for Tmax, WB and PDSI were averaged (Tmax, PDSI) or summed (WB) to seasonal values for winter (December-February), spring (March-May), summer (June-August) and autumn (September-November). The considered window for exploring the relations between climate and tree growth were from June of the previous year (Jun(-1)) to September of the current year (Sep) for monthly values; while for seasonal values they ranged from summer of the previous year (Sum(-1)) to autumn of the current year (Aut). Additionally, annual values were also calculated by averaging or summing monthly values from previous October (Oct (-1)) to current September (Sep).

Chronology computation and assessment

The intra- and inter-annual responses of growth to climate were investigated after standardizing the raw EW, LW and TR series with the ARSTAN computer program (Cook and Holmes 1996). Asynchronous growth changes such as disturbance signals due to natural canopy opening or logging were unusual within our tree-ring series, and only 39 years of tree ring data were available. Therefore, a flexible spline function for standardization guarantees the removal of most non-climatically related variance, such as the biological trends, by preserving high-frequency climatic information (Cook and Peters 1981). A spline with a 50% frequency response of 32 years was fitted to the series, and the residuals obtained were pre-whitened by autoregressive modeling, yielding dimensionless indices that represent independent records of growth. The final

chronologies were calculated as the robust biweight mean of the obtained stationary indices.

The statistical quality of the chronologies was assessed for 1967–2005, the common period of all chronologies, using standard basic statistics to measure the common signal. Mean sensitivity (MS) indicates the mean relative change between consecutive ring widths, signal-to-noise ratio (SNR) reveals the strength of the observed common signal among trees, and expressed populations signal (EPS) quantifies the degree to which the obtained chronology represents the theoretically perfect chronology (Briffa and Jones 1990; Fritts 2001). Moreover, the LW to TR ratio (LW/TR) in percent value, and the correlation between EW and LW chronologies (R_{EL}) indicating the intra-annual consistency of growth behavior, were also calculated.

Spatial variability in tree growth and climate responses

Common patterns of growth behavior within our tree-ring network were explored using principal component analysis (PCA) on the TR index chronologies of the ten stands for the common period 1967–2005. PCA transformed our collection of tree-ring chronology indices into a new set of principal components (PC), calculated on the covariance matrix of the original data. Orthogonal rotation of the PC axes was performed according to the Varimax criterion, which maximizes the spread of original PC loadings (Legendre and Legendre 1998). A scatter plot of the weighting coefficients for the first two PCs displayed the clusters of chronologies with similar growth variation. Principal component analysis was performed with the SPSS v15.0 package (SPSS Inc., Chicago IL, USA).

Stands with similar growth behavior were grouped to calculate composite chronologies. All individual tree-ring series from stands belonging to the same cluster

were pooled, standardized and averaged with ARSTAN as previously described for the stand chronologies, giving a group chronology for each of EW, LW and TR, composed of trees from several stands (Carrer et al. 2007). Descriptive statistics (MS, SNR, EPS, R_{EL} and LW/TR) were also calculated for the composite chronologies in the common period 1967–2005.

In order to identify the main climatic variables that influenced growth at a local scale within the recognized groups, we calculated Pearson's correlations between EW, LW and TR composite chronologies and climatic variables obtained after averaging the climatic series from the $0.5^\circ \times 0.5^\circ$ grid boxes corresponding to each group in the periods 1967–2005 for Tmax and WB, and 1967–2002 for cloud cover and PDSI.

The pure and shared effects of each climatic factor on the composite chronologies and the total variance explained by climate were assessed using redundancy analysis (RDA), which seeks linear combinations of environmental factors that are correlated to linear combinations of response variables (Legendre and Legendre 1998). A sequence of several complementary RDAs was performed with the software CANOCO v4.0 for Windows (ter Braak and Smilauer 1998). The forward selection procedure after 9,999 Monte Carlo random permutations allowed excluding highly redundant and collinear climatic variables, which could have caused model instability and/or variance overestimation. Stepwise RDA was performed to know the explained tree-ring growth variation for the previously selected climatic predictors within each of the components Tmax, WB and PDSI. To assess the shared variation between Tmax, WB and PDSI, the pure growth variance explained by each component was determined by RDA, while partial RDA (pRDA) determined the shared variation with each of the other components considered as covariables (Legendre and Legendre 1998). The amount of growth variance explained in each step was calculated as the proportion of total variance given

by the canonical eigenvalue λ . The total explained variation in composite chronologies for the different recognized groups was obtained by RDA including all the significant predictors under a reduced model. For all described analyses, Monte Carlo tests with 9,999 random permutations were used to evaluate the significance of canonical eigenvalues. A scatter plot of the weighting coefficients for the first two RDA axes of an overall canonical ordination displayed the relationships between all composite chronologies for EW, LW and TR, and the significant climate predictors at a regional scale.

Results

Characteristics of trees and tree-ring chronologies

Mean DBHs of dominant trees in the sampled stands varied between 29.6 and 66.7 cm, and mean estimated ages between 33 and 55 years (Table 1). Earlywood was wider than latewood at all stands, with mean LW/TR ratios ranging between 30 to 45.6% (Table 2). The relative change between consecutive rings was higher in LW than EW series at all stands, as indicated by the MS values, which were lower for TR chronologies. MS values were negatively correlated to elevation, but only significant for EW ($R = -0.64$, $P = 0.044$) and TR ($R = -0.72$, $P = 0.018$). The strength of the common signal within each stand was larger in TR than in EW and LW, as indicated by the SNR statistic, which ranged 2.91–19.11 for TR, 2.37–12.59 for EW, and 1.07–13.00 for LW. EPS values were mostly higher than 0.85 with few exceptions, suggesting that the amount of local year-to-year growth variation shared by trees was relatively high, especially for TR series. EW and LW growth variations were significantly correlated in all cases, with R_{EL} ranging between 0.45 ($P < 0.01$) and 0.72 ($P < 0.001$). Consequently, common

signal among trees was site-dependent, with the same sites showing high EPS values for EW, LW and TR, but with a greater common signal for TR.

Geographical variation of tree-ring growth and its climatic response

The scatter plot for the two first PCs revealed three consistent groups of stands, with PC1 and PC2 explaining 36.6% and 29.7% of the total tree-ring growth variation, respectively (Fig. 2). A first group comprised three stands (COR, INS, MUR) in the west (W) of Galicia, a second group included four stands (ALO, BAR, VER, VIG) in the south (S), and a third group comprised three stands (CAP, MCU, TRA) in the north (N).

Composite chronologies of each of the three groups revealed a large amount of growth variation shared by the trees at a regional level. Thus, EPS values of the composite EW, LW and TR chronologies were higher than 0.85 in all cases (Table 2), and chronologies of EW and LW were similar within each group (Fig. 3), with R_{EL} ranging between 0.64 and 0.69 ($P < 0.001$).

Correlations with climate indicated significant influences of Tmax, WB and PDSI on tree growth, with similar patterns among EW, LW and TR within each group, but contrasting signs and seasonality of the relationships among the three recognized groups (Fig. 4). Group W showed negative correlations for Tmax during January, spring and summer, and also for annual Tmax, and particularly pronounced in EW and TR (Fig. 4A). An even more remarkable response was found when considering water availability. Thus, positive responses to WB were strong, mainly for the whole year, but also from previous winter to summer; and to PDSI from previous autumn to spring, with EW being sensitive to PDSI in previous September-November, when water availability did not affect LW growth. As regards group S, the negative influence of Tmax and positive

of WB was found in previous October for all tree-ring compartments, and only for LW and TR in July (Fig. 4B); response to PDSI was positive in previous September, and from May to August, but mainly focused on LW and TR chronologies.

The results were different for group N, especially as regards the observed responses to water availability. Tmax influenced growth only negatively in previous October, and positively for EW and TR in January (Fig. 4C). Responses to WB and PDSI were negative, and mainly concentrated in previous winter and spring. More specifically, EW was significantly correlated to WB in December-March, LW in February, and TR in February-March, while all three chronologies had significant correlations with PDSI from February to April.

RDA and pRDA models allowed excluding redundant and collinear climatic variables, assessing the pure growth variance explained by T, WB and PDSI, and estimating the shared variation between each of these components (Table 3). According to RDA models, the most important climatic variables for tree growth in group W were Tmax in spring and July, WB in July and the whole year, and PDSI in February, with WB explaining the greatest amount of growth variation; pRDA models showed a significant shared effect of Tmax with both WB and PDSI, but no shared effect between PDSI and WB. In group S, Tmax in previous October and July, WB in the same months and PDSI in previous September and June were the main climatic variables driving radial growth, with no significant pRDA models, which suggests non-shared variation between the climatic variables. In group N, Tmax in previous October and January and WB and PDSI in February significantly influenced tree growth, but among them, uniquely PDSI and Tmax showed a shared effect on growth variation. According to the reduced RDA models, 54.9%, 42.2% and 42.0% of tree growth variation in groups W, S and N, respectively, was explained by the considered climatic variables.

Climatic responses at a regional scale

According to an overall RDA model (F -value = 4.84, $P < 0.001$), the climate variables with a significant effect on tree growth also showed significant correlations with the two first RDA axes (Table 4). Axis 1 explained 50% of the growth-climate relationships and was negatively correlated with July Tmax, while annual WB and June PDSI showed positive correlations with this axis. Axis 2 explained 44.5% of the growth-climate relationships and was positively correlated with Tmax in previous October and PDSI in February and April. The ordination obtained showed that tree-ring growth in group W was positively related to annual WB and negatively to July Tmax (Fig. 5). Group S was positively related to Jun PDSI, and group N negatively to February and April PDSI, while both groups were negatively related to Tmax in previous October. Among these, the most important predictors showing significant correlations with tree-ring growth were annual WB for group W (Fig. 6A), and July PDSI for group S (Fig. 6B), both of them with a positive relationship; and Feb PDSI for group N, with a negative relationship (Fig. 6C). Tree-ring growth in group N was also negatively related to cloud cover in February-April ($R = -0.52$, $P = 0.001$), while growth in other groups was independent of it.

Discussion

Despite the relatively reduced extension of the study area, we identified contrasting patterns of growth variability and climate sensitivity for *Pinus pinaster* related to the geographical gradients and differences in climatic regimes within our tree-ring network. The dependence of MS on stand elevation indicated that this is a main physiographic

factor controlling growth variability of *P. pinaster* in Galicia. Stands at a lower elevation had higher MS in both EW and TR, i.e., higher year-to-year variability in tree-ring chronologies, suggesting that the effects of environmental factors limiting inter-annual variations of cambial activity decrease with increasing elevation. The reduced MS at a higher elevation is also probably a consequence of a shorter growing season imposed by lower temperatures (Chhin et al. 2008; Leal et al. 2008; Lo et al. 2010). These results agree with previous studies that found strong differences in *P. pinaster* growth patterns between coastal (low elevation) and inland (high elevation) areas of Galicia (Álvarez González et al. 2005).

The spatial coherency of climate sensitivity within the identified groups supports previous evidences from other conifers that similar growth responses may be expected within climatically homogeneous areas (Carrer et al. 2007; Littell et al. 2008). The multivariate analyses of our tree-ring chronologies generated three groups of stands characterized by their geographical distance to the littoral, and to the boundary between the Atlantic and Mediterranean biogeographical regions, which is coherent with the described patterns of water regime throughout the year (Martínez Cortizas et al. 1994). Groups W and S are similar to each other, and comprise sites located close to the western Atlantic coast or southern Galicia where, respectively, higher temperatures due to low elevation or the more Mediterranean conditions of the southern inland can lead to periods of low water availability, though less remarkable than under a proper Mediterranean climate. In contrast, group N clearly separates from these stands, and includes sites in northern Galicia, where water deficit is considerably reduced as a result of the combination of lower temperatures, recurrent fog, and abundant precipitation.

Trees in groups W and S show generalized negative responses to Tmax and positive responses to WB and PDSI, suggesting that water stress limits *P. pinaster*

growth in western and southern Galicia. This result confirms previous expectations that radial growth of *P. pinaster* is mainly limited by water deficit prior to and during the active period, with characteristic positive effects of moister winter, spring and summer (Bogino and Bravo 2008; Rozas et al. 2009; Vieira et al. 2009). This situation is particularly clear in group W, where pine growth was dependent on annual water balance and soil water availability in spring, and also showed a stronger climatic signal than the other groups. The positive effect of moist previous autumns on EW growth in group W, and on TR in group S, could be a consequence of sustained photosynthetic activity at the end of the active season, resulting in a greater amount of carbohydrates stored to be used in the following active season (Zweifel et al. 2006).

Furthermore, negative relationships between Tmax and growth were generalized for group W, and in July for LW and TR in group S, probably due to water deficit generated by elevated temperatures in spring and summer. *P. pinaster* has a high water use efficiency in comparison to other pine species, especially mesic genotypes under humid environments, where relatively high levels of rainfall guarantee vigorous growth (Martínez-Vilalta and Piñol 2002; Tognetti et al. 2000). Common garden experiments have revealed that Atlantic populations of *P. pinaster* have a better water use efficiency and growth potential than Mediterranean ones, being able to maintain high growth rates even under moderate water stress (Correia et al. 2008). This, together with the characteristic high growth plasticity of *P. pinaster* Atlantic populations (Chambel et al. 2007), can explain the observed negative growth responses to Tmax, and positive to WB and PDSI in previous autumn, winter, spring and summer for both groups.

As regards group N, prolonged cloudiness, frequent fogs and abundant precipitation in northern Galicia (Martínez Cortizas et al. 1994), can explain the positive effects of elevated Tmax in January, and the detrimental effects of WB, PDSI and cloud cover in

winter and spring. Positive influence of high winter temperatures on pine growth have been previously interpreted as a consequence of the damage produced by freezing embolism and ice formation within the buds, with enhanced growth if they do not occur (Chhin et al. 2008; Parker et al. 2001). However, such freeze events are not expected in the study area, and snow typically occurs only at higher elevations, above the upper limit of *P. pinaster* in Galicia. In this case, the larger growth of *P. pinaster* can result from winter photosynthesis stimulated by elevated temperatures (Medlyn et al. 2002); carbon gain in winter can be allocated for growth in the following active season, which can partially explain the negative influence of water availability as an indirect effect of lower daily temperatures. The observed negative effect of water availability in late winter-spring has been previously noticed in other conifers under wet climates, such as in north-central Europe and north-western North America (Chhin et al. 2008; Mäkinen et al. 2002; Peterson and Peterson 2001; Watson and Luckman 2002). *P. pinaster* is a Mediterranean species adapted to harsh summer droughts (Martínez-Vilalta and Piñol 2002), and may be susceptible to soil water saturation and oxygen deprivation in the rhizosphere that could negatively impact nutrient uptake. However, to our knowledge, the effects of water-logging on its physiology and growth have not been studied yet; but the known adverse effects of water-logging stress on the growth and survival of *P. elliottii* var. *densa* in Florida, USA (Ford and Brooks 2002), supports this interpretation. Additionally, cloudiness associated with rainy periods can notably reduce solar radiation, photosynthetic rates and the amount of photosynthates assimilated, as seems to be the case for February-April in northern Galicia. This interpretation is supported by previous evidence that reduced solar radiation, modulated by cloudiness frequency and duration, was a primary factor limiting photosynthesis, carbon uptake and growth during the rainy season in a tropical tree (Graham et al. 2003).

Our results suggest that conditions modulating growth activity in autumn controlled the amount of carbohydrate reserves at the end of the growing season. Climatic conditions in previous October influenced growth in groups S and N, manifested as negative response to T_{max} in both groups and positive to WB in group S. Similar results on the detrimental effects of elevated temperatures in previous autumn were found in other conifers, such as *Picea abies* in northern Europe (Mäkinen et al. 2002) and *Pinus nigra* in southwest Europe (Lebourgeois 2000; Martín-Benito et al. 2010). This suggests an additional preconditioning effect related to the amount of reserves stored for the following growing season. Carbon assimilation in *P. pinaster* can occur year round, and changes in the response of stomatal conductance to vapour pressure can cause a seasonal acclimation in photosynthetic temperature response (Medlyn et al. 2002); this acclimation allows relatively high rates of photosynthesis under warm conditions. In pine species, non-structural carbohydrates and lipids built up in autumn, when radial growth has already ceased, are stored throughout the winter to be used in the following active season (Hoch et al. 2003). A warm-moist October would increase respiration rates and/or delay the end of the growing season, and therefore reduce the amount of stored reserves (Lebourgeois 2000).

Although the different ecological and physiological mechanisms causing a link between environmental variability and tree growth or directly modulating tree growth behavior may be strongly site dependent (Loehle and LeBlanc 1996; Rathbeger et al. 2005), the results presented here indicate a clear and robust geographic structure of the sensitivity of *P. pinaster* growth to climate variation within the studied region. Climate appears as a main factor driving tree growth, although other site and stand factors have been shown to be also very relevant in controlling tree growth under temperate conditions (Leonelli et al. 2009; Lo et al. 2010). *P. pinaster* has very plastic

physiological responses to particular combinations of climatic factors, which can largely vary among (Alía et al. 1997; Chambel et al. 2007) and within populations (Zas et al. 2004). In addition, most *P. pinaster* stands in Galicia derive from plantations established by the Forest Administration in the 1940s to 1970s, which were performed with different seed-sources from a wide variety of Iberian provenances (De la Mata and Zas 2010a). Consequently, some of the study stands could include genotypes presumably not adapted to the local climatic conditions, i.e., with a higher drought tolerance, a lower growth potential and/or a lower water use efficiency than local mesic Atlantic provenances (Correia et al. 2008; De la Mata and Zas 2010b; Tognetti et al. 2000). Unfortunately, we were not able to determine the origin of the genetic material in these stands, and then further studies are necessary in which the role of the genetic variation is accounted for.

Conclusion

Growth responses of *Pinus pinaster* to climatic variation showed a clear geographically structured pattern, with three groups of closed sites showing different climate sensitivities. This suggests that the variability of climate regimes is important for *P. pinaster* growth within the study region near the transition between the Atlantic and Mediterranean regions. The combination of elevated maximum temperatures and reduced soil water availability is detrimental for tree performance in western and southern Galicia, where summer water deficit is more pronounced. This is a similar response to those previously described for other pine species growing at low elevations under temperate climates (Lebourgeois 2000; Parker et al. 2001). On the other hand, conditions related to water surplus during winter and early spring cause growth reduction in areas where a period of summer drought, typical of Mediterranean climate,

is absent. Further investigations on the climate sensitivity of tree-ring growth combined with the characterization of population genetics and studies performed on common garden genetic trials, would inform us about the adaptive value of the observed responses to the ecological conditions existing in NW Spain.

Acknowledgements We thank N. Bermejo, A. González, S. Lamas, P. Manso, B. Rodríguez-Morales and A. Soliño for field and laboratory assistance. The personnel from Dirección Xeral de Montes, Forest Districts and Islas Atlánticas National Park facilitated site accession. V. Rozas benefited from research contracts by INIA-Xunta de Galicia and CSIC. This research was funded by Dirección Xeral de Investigación, Desenvolvemento e Innovación, Xunta de Galicia (PGIDIT06PXIB502262PR).
