[1] Mantle xenoliths provide our clearest look at the magnetic mineral assemblages below the Earth's crust. Previous investigations of mantle xenoliths suggested the absence of magnetite and metals, and proposed that even if such minerals were present, they would be above their Curie temperatures at mantle conditions. Here we use magnetic measurements to examine four exceptionally fresh suites of xenoliths, and show that magnetite occurs systematically, albeit in variable amounts depending on the tectonic setting. Specimens from low geotherm regions hold the largest magnetic remanence. Petrographic evidence shows that this magnetite did not form through serpentinization or other alteration processes. Magnetite, which is generally stable at the P-T- fO_2 conditions in the uppermost mantle, had to have formed either in the mantle or, less likely, in the volcanic conduit. In some cases, the source of the xenoliths was at temperatures <600°C, which may have allowed this portion of the lithospheric mantle to carry a magnetic remanence. Whether such magnetite carries a remanent magnetization or is simply the source of a strong induced magnetization, these new results suggest that the concept of the Moho as a major magnetic boundary needs to be revisited. **Citation:** Ferré, E. 1. Introduction

[2] Previous investigators viewed the Moho as a fundamental boundary separating the magnetized crust from the non-magnetic mantle [Wasilewski *et al.*, 1979; Wasilewski and Mayhew, 1992]. This model, central to the interpretation of aeromagnetic and satellite data, argues that the mantle does not contain ferromagnetic phases capable of carrying

a magnetic remanence. Even if present, such minerals would be above their respective Curie temperatures (T_c) and they would contribute negligibly to long wavelength magnetic anomalies (LWMA). Numerous studies applied this model widely across all tectonic settings [e.g., Maus *et al.*, 2007].

[3] Recent observations suggest that this model ought to be revisited. First, studies on the spectral structure of aeromagnetic anomalies suggest that the forearc mantle may carry a significant remanence [Cascadia: Bostock *et al.*, 2002; Blakely *et al.*, 2005]. Other reports of magnetization in the upper mantle include the Ligurian Sea [Chiozzi *et al.*, 2005], the Caribbean Sea [Counil *et al.*, 1989] and other oceanic basins [Arkani-Hamed and Strangway, 1987]. The non-magnetic mantle model neglects the fact that portions of the lithospheric mantle cool below the Curie temperature of magnetite, including tectonic settings with depressed geotherms (subduction zones, cratons, and old oceanic lithosphere). Second, determinations of fO_2 in the upper mantle support the stability of magnetite above the wüstite-magnetite buffer [Frost and McCammon, 2008; Goncharov *et al.*, 2012]. Third, many xenoliths used in earlier studies [Wasilewski *et al.*, 1979; Wasilewski and Mayhew, 1992] were contaminated by their host basaltic melt, altered by supergene fluids, or were atypical of bulk mantle composition. The forthcoming launch of the Swarm satellite constellation may contribute to a better understanding of the role of deep magnetic sources [Friis-Christensen *et al.*, 2006] although it is uncertain that relatively small anomalies, such as that in Cascadia, will be resolved at satellite altitude.

[4] Mantle xenoliths provide our clearest view of lithospheric mantle conditions because they ascend through the lithosphere within a few hours [Demouchy *et al.*, 2006], thereby minimizing the opportunity for the formation of secondary magnetic minerals through alteration. Magnetite may form in olivine and pyroxenes through exsolution at mantle conditions [Sen and Jones, 1988], or by crack healing and metasomatism during xenolith ascent [Drury and van Roermund, 1988]. Despite their rapid ascent, xenoliths may be contaminated by the host magma along cracks and mineral grain boundaries. Similarly, hematite can grow along grain boundaries during supergene alteration. Notwithstanding these processes, unaltered mantle xenoliths still provide the best available record of upper mantle magnetic mineralogy, and we have taken every precaution to avoid altered xenoliths in this study.

2. Petrography of four series of fresh mantle xenoliths

[5] Previous petrological and mineralogical studies constrain the eruption age, the pressure, temperature and redox equilibration conditions for each of the four xenolith suites:

Figure 1. Scanning electron microscope images of thin sections of peridotite xenoliths. (A) Secondary electron image of a harzburgite xenolith from Avacha volcano, Kamchatka arc. The rock is free of post-eruptive alteration along grain boundaries. Olivine (Ol) grains host 200 nm x 500 nm, needle-shaped magnetite (Mag) inclusions adjacent to orthopyroxene (Opx) exsolution lamellae. (B) Backscattered electron (BSE) image of a garnet harzburgite xenolith from Udachnaya kimberlite, Siberian craton [LOI=0.04, *Ionov et al.*, 2010]. A few Ol grain boundaries have 10–20 μm -thick layered rinds of serpentine (Srp) including nickel sulfides (NiS). (C) BSE image of lherzolite xenolith from French Massif Central volcano. Ol and diopside (Di) grains display exsolved Cr-rich spinels (Sp), adjacent to exsolved amphibole (Amp) lamellae. (D) BSE image of lherzolite xenolith from Salt Lake volcano, Hawai'i. Di grains host inclusions of feldspar (Fsp) and apatite (Ap). Exsolved Mag occur within Di and along Opx-Amp grain boundaries.

Kamchatka island arc [*Ionov*, 2010], Siberian craton [*Ionov et al.*, 2010; *Goncharov et al.*, 2012], French Massif Central continental plume [*Lenoir et al.*, 2000], and Hawai'i oceanic hot spot [*Sen*, 1988].

[6] Within each xenolith suite, samples met the following criteria: i) xenoliths were larger than 80 mm in diameter, ii) 10 mm cubic specimens were extracted from near each xenolith's center which lacked any visible alteration, and iii) all xenoliths were free of inclusions and veins of host magmatic rocks. A third of the samples passed these tests. This protocol excludes xenoliths with obvious alteration and contamination, and yields macroscopically unaltered and uncontaminated xenoliths.

[7] Additional screening involves measuring loss-on-ignition (LOI), which is caused by loss of volatile components (OH, S, CO_2 , Cl) during heating, and is broadly interpreted to reflect the degree of serpentinization. Only specimens with LOI < 1.00 weight % were included for further investigation, which eliminates excessively altered samples. In addition, the xenolith samples selected from the French Massif Central collection display an Alt-S% < 10%, indicating a low degree of alteration of their primary sulfides [*Alard et al.*, 2011].

[8] The main silicate phases (olivine, orthopyroxene, clinopyroxene) exhibit limited chemical core-to-rim zonation [*Sen*, 1988; *Lenoir et al.*, 2000; *Ionov*, 2010; *Goncharov et al.*, 2012]. This absence of zonation attests to equilibration at high temperature and indicates that mineral assemblages observed in the studied xenoliths likely represent ambient mantle conditions. The short ascent duration typically reported for mantle xenoliths, as well as the large size of our samples,

limits opportunities for xenolith re-equilibration with their host magmas [e.g., *Demouchy et al.*, 2006; *Peslier et al.*, 2008].

[9] In several specimens (e.g., iAv-9b, SAL), elongated grains of magnetite (≈ 0.5 to $1 \mu\text{m}$) occur within olivine and pyroxene in orientations parallel to distinct crystallographic planes within their silicate host (Fig. 1). This suggests that these magnetite grains formed either at mantle depths or during the xenolith ascent, but not through post-eruption reaction with hydrous fluids.

3. Magnetic properties of mantle xenoliths in different tectonic settings

[10] Details on magnetic methods are given in the Appendix. Each xenolith sample yielded two 10-mm cubic specimens for magnetic analyses. Stepwise demagnetization of the natural remanent magnetization (NRM) was performed using alternating field up to 120 mT. The least altered specimens showed a single component of NRM and were kept for further tests. A few specimens' NRM demagnetization spectra displayed an additional high coercivity component, inferred to be carried by hematite, and were discarded because this mineral indicates that the specimen's original mineral assemblage was compromised by oxidation.

[11] All mantle xenoliths show a relatively narrow range of magnetic susceptibilities and a broad range of NRM values (Figure 2A; Supporting Information). The magnetic susceptibilities are consistent with a log normal distribution (Supporting Information). Low-field magnetic susceptibility (K_m) is a proxy for the concentration and grain size of

Figure 2. (A) Natural remanent magnetization vs low-field magnetic susceptibility of peridotite xenoliths (see also Supporting Information). Koenigsberger ratio, $Q_n = \text{NRM} / K_m H$ where H : local geomagnetic field intensity = 40 Am^{-1} . Each suite shows a relatively narrow range of K_m and a broad range of NRMs. (B) H_{cr}/H_c vs saturation magnetization (normalized to mass, in $10^{-6} \text{ Am}^2/\text{kg}$). Specimens from low geotherm settings display lower average H_{cr}/H_c ratios and lower M_s .

ferromagnetic minerals, and to a lesser degree, the concentration of paramagnetic minerals. The NRM intensity of mantle xenoliths varies broadly between 10^{-4} and 1 A/m , and is an expression of the abundance of single domain and pseudo-single domain sized grains in a specimen, as well as the strength

of the Earth's magnetic field at the time of magnetization. The Koenigsberger ratio (Q_n) represents the ratio of natural remanent magnetization to the induced magnetization in the Earth's field: $Q_n = \text{NRM} / K_m H$, where K_m is the magnetic susceptibility in SI units and H is the local geomagnetic field intensity (here 40 A/m). Values higher than 1 indicate that the specimen's remanent magnetization will be the dominant contribution to magnetic anomalies, while values less than 1 indicate that the specimen's induced magnetization will be the primary contribution. Approximately one third of the xenoliths display Q_n values >1 , and if these specimens are representative of magnetic mineral assemblages in the lithospheric mantle, then these measurements suggest that the mantle's remanent magnetization may contribute to magnetic anomalies in low geotherm regions. Although there is a significant amount of overlap in the magnetic properties of xenoliths from different tectonic regions, on average, specimens from the Siberian craton and Kamchatka arc have higher NRM intensities than those from the Massif Central plume or the Hawai'i hot spot. Xenoliths from the Kamchatka subduction zone have the highest Q_n values and their remanent magnetizations may play a more important role than their induced magnetizations in long wavelength magnetic anomalies. Importantly, the Kamchatka xenoliths are free of any post-eruption alteration [Ionov, 2010].

[12] The saturation magnetization normalized to mass (M_s) constitutes a proxy for the concentration of ferromagnetic minerals in the xenoliths. The ratio of the coercivity of remanence (H_{cr}) to the bulk coercivity (H_c) is directly related to the median grain size of a specimen's ferromagnetic minerals. Although the values of magnetic hysteresis parameters significantly overlap between suites, they plot in different regions of the M_s vs H_{cr}/H_c diagram (Fig. 2B; Supporting Information). The magnetic properties of fresh mantle xenoliths vary with tectonic setting (Fig. 2; Table).

4. Identification of the main ferromagnetic phases

[13] All specimens produce major hysteresis loops that show the presence of at least one ferromagnetic phase. This ferromagnetic contribution varies between 1 and 70% of the bulk magnetic susceptibility with an average of 21% (Table 1; Supporting Information).

[14] Certain candidate minerals can be ruled out. Cr-rich spinel behaves ferromagnetically only within a specific compositional range [Schmidbauer, 1983], and in these mantle xenoliths the iron content of Cr-rich spinel is too low to carry a magnetic remanence. Iron-nickel sulfides, such as pentlandite, cannot contribute to remanence because they are paramagnetic at and above room temperature. The lack of a pyrrhotite transition around 30–34 K in low-temperature (LT)

Table 1. Magnetic properties of peridotite xenoliths in four distinct tectonic settings including (i) arithmetic mean magnetic susceptibility, (ii) average of the magnetic remanence vectors, (iii) Koenigsberger ratios calculated from the intensity of the resultant mean remanence vector and the mean magnetic susceptibility.

xenolith suite	low-field susceptibility ($10^{-6} [\text{SI}]$)					NRM ($10^{-3} [\text{A/m}]$)					Qn			
	<i>n</i>	min	max	mean	stdv	<i>n</i>	min	max	mean	stdv	min	max	mean	error

experiments, even in the specimens with high sulfur content [≈ 600 ppm; *Alard et al.*, 2011], shows that the contribution of pyrrhotite to remanence is negligible. Finally, Fe-Ni alloys were not observed during either the electron microscopic study or the rock magnetic measurements.

[15] Pure magnetite is the ferromagnetic mineral most commonly observed in mantle xenoliths. In measurements of room temperature saturation isothermal remanent magnetization (RT-SIRM) on cooling from 300 K to 10 K, specimens from all four xenolith suites showed $\delta M/\delta T$ maxima at 120–125 K (Fig. 3A), which corresponds to the Verwey transition of pure magnetite [e.g., *Walz*, 2002]. This data, along with the electron microscopy results and alternating field demagnetization spectra of NRM (Supporting Information), indicate that magnetite constitutes the dominant NRM carrier. The xenolith's hysteresis properties (Fig. 3B), are consistent with pseudo-single domain (PSD) to single domain (SD) grain sizes for this magnetite.

[16] Two samples from the Siberian craton (U503 and U504) also displayed clear pyrrhotite transitions around 30–34 K in the low temperature cycling experiments. Thus, although magnetite may be the most frequently observed ferromagnetic mineral in mantle xenoliths, pyrrhotite may also occur on a less frequent basis. However, its

comparatively low Curie temperature of 320°C makes it unlikely that pyrrhotite contributes to either an induced or remanent magnetization in the lithospheric mantle.

5. Origin of magnetite in mantle xenoliths

[17] In mantle peridotites, magnetite is commonly thought to form as a secondary phase through serpentinization at various depths: in the mantle [e.g., *Facer et al.*, 2009], at intermediate depths or near the surface [e.g., *Toft et al.*, 1990]. However, in this study we argue that magnetite can form via diffusive exsolution at mantle depths within both olivine and pyroxene, as well as along primary silicate grain boundaries (Fig. 1). Our strongest evidence for such a claim is magnetite inclusions exsolved in olivine (and frequently associated with orthopyroxene) in xenoliths from Kamchatka. These inclusions are similar to those described by *Markl et al.* [2001], who proposed a formational mechanism associated with a late stage rise in *oxygen fugacity* conditions. Indeed, spinel grains in the Kamchatka xenoliths show an increase in Fe^{3+} from core to rim, consistent with an increase in $f\text{O}_2$ due to exposure to late-stage, subduction-related fluids [*Ionov*, 2010; *Goncharov et al.*, 2012]. These inferences are consistent with data on melt inclusions in spinel from the Kamchatka xenoliths, which trapped low-T melts linked to highly oxidized hydrous fluids expelled from subducted slab [*Ionov et al.*, 2011]. Such oxidizing fluids can be present at mantle depths and may explain the magnetite observed in the other xenolith suites. In the Hawai'i xenoliths, a portion of the magnetite grains are spatially associated with amphibole lamellae, in striking similarity with the inclusions described in gabbroic olivines altered at high temperature by oceanic hydrous fluids [*Puga et al.*, 1999]. Similarly, in the Massif Central xenoliths, the amphibole lamellae exsolved along crystallographic planes in clinopyroxene suggest the availability of H_2O during exsolution. Our sample selection criteria exclude almost all cases of xenolith serpentinization, however when rare serpentine veins were observed, they do not host magnetite or metal alloys, but only non-ferromagnetic nickel sulfides.

[18] The magnetite exsolution observed in this study is thought to occur during oxidation, at temperatures higher than 600°C, and has been previously studied in pyroxene [*Schlinger and Veblen*, 1989] and in olivine [*Kohlstedt et al.*, 1976; *Putnis*, 1979; *Franz and Wirth*, 2000; *Markl et al.*, 2001]. In olivine, these exsolved grains tend to display both needle-like and dendritic morphologies and display high coercivities [*Brewster and O'Reilly*, 1988]. In mantle xenoliths from a seamount, *Franz and Wirth* [2000] attributed the olivine oxidation event responsible for magnetite exsolution to a 700–800°C metasomatic fluid. The exsolved magnetite observed in this study occurs within primary silicates, away from serpentine veins, and is consistent with formation at mantle depths or during the initial stages of ascent.

6. Potential implications for sub-Moho magnetic sources

[19] The single component NRM measured in the mantle xenoliths of this study is typical of that acquired through a thermoremanent magnetization process. This NRM was acquired upon cooling of the mantle xenolith at or near the surface of the Earth. These room temperature remanence

Figure 3. (A) First derivative of magnetization with temperature vs temperature for eight peridotite xenoliths. The 120–125 K Verwey transition shows the presence of magnetite. This data, along with hysteresis properties (Supporting Information), illustrates that PSD to SD magnetite dominates the NRM. (B) *Dunlop* [2002] plot of all xenolith specimens.

values represent a two to three fold increase with respect to their remanence at depth. In cold geotherm settings, prior to eruption, the mantle source regions were cooler than the melts that transported xenoliths to the Earth's surface. The Curie temperature of pure magnetite increases with pressure/depth [Schult, 1970], such that T_c is 600°C at 1 GPa. In cold geotherm settings such as subduction zones (e.g., the Kamchatka arc) and cratons (e.g., Siberia), this pressure dependence may push the Curie depth below the crust-mantle boundary.

[20] Assuming a geotherm of 25°C/km, any magnetite present in the mantle would be at temperatures well above its Curie temperature. However, if a geotherm typical of forearc mantle wedges is assumed [e.g., 12°C/km, Bostock *et al.*, 2002], then the Curie depth could be as deep as 50 km. Such an arc setting could potentially yield a 10 km-thick layer of 'magnetically cold' uppermost mantle. In this way, the lithospheric mantle may significantly contribute to LWMA, whether it is serpentinized [Blakely *et al.*, 2005] or not [Evans, 2010]. In the most permissive circumstances, with a geotherm of 9°C/km (i.e., surface heat flow of 35–40 mW/m²), such as that of the Siberian craton [Goncharov *et al.*, 2012] and a crust-mantle boundary at 40 km depth, the layer of potentially magnetized lithospheric mantle could be up to 25 km thick.

[21] These results demonstrate that the lithospheric mantle displays non-uniform magnetic properties across tectonic settings. The present collections of uppermost mantle rocks are insufficient to produce measurable satellite anomalies but are suggestive of source regions that may significantly contribute to LWMA. Previous work showed that certain lower crustal rocks exhibit high NRM intensities, $>5 \text{ Am}^{-1}$, and elevated Q_n (from 2 to 7), which strongly contribute to some aeromagnetic anomalies [Robinson *et al.*, 2002; McEnroe *et al.*, 2004]. However, in these locations, lacking prominent regional anomalies, NRM intensities appear too modest to contribute to LWMA [Pilkington *et al.*, 2006; Liu *et al.*, 2009; Dunlop *et al.*, 2010].

[22] The measured properties of mantle peridotites would produce magnetization contrasts around 0.02 to 0.03 A/m, resulting in peak-to-trough anomalies of 0.08 to 0.10 nT at 300 km altitude for a 10-km thick slab of magnetized mantle. Although these anomalies remain below the noise level of current magnetic satellites, such features will likely become detectable by the future SWARM satellites.

[23] Although the magnetization of uppermost mantle rocks may appear relatively weak it may provide a supplemental source in areas where crustal magnetizations are too low to explain the observed anomalies. Assuming that all LWMA originate from crustal sources requires crustal sources that are in many cases more strongly magnetized than observations suggest. A magnetized uppermost mantle may provide the missing magnetization. The demonstration of ferromagnetic material in the lithospheric mantle necessitates a re-evaluation of the long held non-magnetic mantle model, and could potentially affect the interpretation of previous and future satellite-derived magnetic data including that from the SWARM mission. In short, deep crustal rocks need not be as strongly magnetized if the upper mantle contributes to long wavelength magnetic anomalies.
