Summary

In a study of the vanadyl (VO^{2+})-humic acids system, the residual vanadyl ion suppressed fluorescence and specific electron paramagnetic resonance (EPR) and NMR signals. In the case of NMR, the proton rotating frame relaxation times ($T_{1\rho}\text{H}$) indicate that this suppression is due to an inefficient H-C cross polarization, which is a consequence of a shortening of $T_{1\rho}\text{H}$. Principal components analysis (PCA) facilitated the isolation of the effect of the VO^{2+} ion and indicated that the organic free radical signal was due to at least two paramagnetic centres and that the VO^{2+} ion preferentially suppressed the species whose electronic density is delocalized over O atoms (greater g -factor). Additionally, the newly obtained variables (principal components – PC) indicated that, as the result of the more intense tillage a relative increase occurred in the accumulation of: (i) recalcitrant structures; (ii) lignin and long-chain alkyl structures; and (iii) organic free radicals with smaller g -factors.

Introduction

Paramagnetic metal ions are frequently present in humic substances and can affect the spectroscopic results obtained, such as NMR (Preston *et al.*, 1984; Preston, 1996; Smernik & Oades, 1999, 2000; Novotny *et al.*, 2006), fluorescence spectroscopy (Senesi, 1990a; Piana & Zahir, 2000; Novotny *et al.*, 2006), and EPR (Jezierski *et al.*, 2000a,b; Novotny & Martin-Neto, 2002; Novotny *et al.*, 2006). Consequently, the interpretation of these spectroscopy results and their correlation with intrinsic characteristics of the samples, such as the degree of humification, can be erroneous. However, by way of these paramagnetic interferences it is possible to carry out studies to probe the binding sites and the functional groups involved (Mangrich & Vugman, 1988; Smernik & Oades, 1999; Novotny *et al.*, 2006), and eventually to unveil more detailed structural information, such as distances apart of functional groups, and the conformations of humic substance (Novotny & Martin-Neto, 2002; Schilling & Cooper, 2004a).

The question arises as to whether or not the effects of paramagnetic ions can be isolated so that the spectroscopic data can be used to elucidate structures of humic substances. Multi-

variate statistics, and especially PCA, provides a useful technique for such (Vandeginste *et al.*, 1998; Novotny *et al.*, 1999, 2007), as will be seen in this communication.

The vanadyl ion (VO^{2+}) has been used as a probe in spectroscopic studies (mainly EPR) of metal ion interactions with humic acids and other macromolecules (Mangrich & Vugman, 1990; Novotny *et al.*, 2006). Organic compounds that have nitrogen and oxygen ligands form very stable complexes with VO^{2+} . However, in vanadyl-humic acid complexes the vanadyl ion is strongly immobilized by bonding to oxygen atoms only (McBride, 1978).

The environmental interest in vanadium has increased because of the reproductive toxicity of vanadium and because of the mutagenic and carcinogenic effects associated with the environmental pollution by this element, which is abundant in crude oils. Although it is found at small concentrations in water, rocks and soils, vanadium has been found to complex readily with humic substances (Mangrich & Vugman, 1990; Senesi 1990b; Lu *et al.*, 1998; Novotny *et al.*, 2006).

The aims of this work are: (i) to isolate the effect of paramagnetic ions on the results of spectroscopic analysis (NMR, EPR and fluorescence) of humic acids extracted from an agricultural soil at an experimental station in Campinas-Brazil (Novotny *et al.*, 2006); (ii) to assess the effect of cultivation on these humic acids; and (iii) to determine which functional groups are directly involved in the complexation of the metallic ions.

Materials and methods

Sample material and extraction of humic acids

The humic acids were extracted from Typic Haplorthox soils, with clay contents between 500 and 650 g kg⁻¹. The soils are from a long-term management systems experiment (15 years old) installed in Campinas, São Paulo State, Brazil (47°05'W, 22°54'S). The management systems were: conventional tillage; minimum tillage; and no-tillage. Crop rotation included maize (*Zea mays*) and soybean (*Glycine max*) in the summer and black oat (*Avena strigosa*) and Sunn hemp (*Crotalaria juncea*) in the winter. Samples were collected at depths of 0–5, 5–10, 10–20 and 20–30 cm, giving a total of 12 samples.

The humic acids were extracted according to the method recommended by the 'International Humic Substances Society' (Swift, 1996).

EPR measurements

Measurements were carried out in duplicate at room temperature (300 K) using an X-Band Bruker EMX EPR spectrometer (Bruker BioSpin, Rheinstetten, Germany) with a modulation frequency of 100 kHz in the magnetic field. The *g*-factor was measured against a standard of 2,2-diphenyl-1-picrylhydrazyl (DPPH) (*g* = 2.0036). For quantitative analysis, EPR quartz tubes (2.5 mm I.D.) were filled to a height of 0.5 cm with humic acids, which corresponds to a sample mass of approximately 30 mg. To quantify the vanadyl ion content in arbitrary units, a ruby crystal was used as a secondary standard, according to Singer's method (see Singer, 1959; Novotny *et al.*, 2006). The signal of the VO²⁺ ion was used because its EPR signal dominated those of the paramagnetic metal ions (Fe³⁺ and Cu²⁺) detected in the samples (Novotny *et al.*, 2006). The integrated signal areas were obtained by the approximation $Y' \Delta H^2$ (Poole, 1983), where Y' is the EPR derivative signal amplitude and ΔH is the peak-to-peak line width. The sixth perpendicular resonance line of the VO²⁺ ion ($M_I = -3/2$) was selected because this was intense and relatively isolated from any other resonance lines in the spectrum. By comparing the areas of the EPR VO²⁺ signals of the samples with the signal areas of standard frozen VO²⁺ solutions, measured at the same experimental conditions, it was estimated that the VO²⁺ ion concentration in the samples was in the range of 20–60 µg g⁻¹.

Solid-state ¹³C NMR spectroscopy

Solid-state ¹³C NMR data were obtained at a resonance frequency of 100.6 MHz using a Varian Inova 400 spectrometer (Varian, Palo Alto, CA, USA). The humic acids samples were placed in a 5-mm diameter cylindrical zirconium rotor with a Kel-F end-cap and spun at 8 kHz in a Doty Scientific MAS probe (Doty Scientific, Columbia, SC, USA). Free induction decay data were acquired with a 40 kHz sweep width, and 512

data points were collected over a 12.8 ms acquisition time. The spectra were acquired with a variable amplitude cross polarization/magic angle spinning VACP/MAS pulse sequence, consisting of a 4 µs preparation ¹H pulse and a contact time of 1 ms. The pulse delay of 500 ms was more than five times longer than the longest ¹H-spin relaxation time, determined with inversion-recovery experiments. To avoid Hartmann-Hahn mismatches due to interfering frequencies at high spinning speeds (Peersen *et al.*, 1993), a ramped ¹H-pulse varying from 110 to 60% of the power level was used. This power range was chosen from pre-experiments where the radio frequency power level was varied until the relative intensities of signals, suppressed with conventional CP/MAS (for example methyl, methoxyl, aryl and carboxyl), were constant. A total of 9600 transients were collected.

Additionally, to verify the mechanism involved in the suppression effect of the vanadyl ion in the NMR signal intensity, the proton rotating frame relaxation times ($T_{1\rho H}$) were determined in six selected samples by a Variable Spin Lock experiment (Smernik *et al.*, 2002). These measurements were carried out using a VACP/MAS pulse sequence in a Bruker DSX 200 NMR spectrometer (Bruker Biospin, Rheinstetten, Germany) (¹³C-resonance frequency: 50.32 MHz) at a spinning speed of 6.8 kHz, a contact time of 0.5 ms with an array of 34 spin-lock times and a pulse delay of 300 ms. This shorter contact time was used to detect better the rapidly relaxing components (Smernik *et al.*, 2002). The area under the various chemical shift regions – alkyl (0–45 p.p.m.), methoxyl, N-alkyl (45–59 p.p.m.), O-alkyl (59–91 p.p.m.), di-O-alkyl (91–109 p.p.m.), aryl (109–143 p.p.m.), O-aryl (143–156 p.p.m.), and carboxyl, amide (156–186 p.p.m.) – were used for the fitting. Single and two component models were fitted, and the best model was determined according to the *F*-test (Smernik *et al.*, 2002).

Fluorescence spectroscopy

The fluorescence spectra were obtained using a PerkinElmer LS50B luminescence spectrometer (PerkinElmer, Waltham, MA, USA). The humic acids were solubilized in 0.05 mol litre⁻¹ NaHCO₃ (pH = 8.5) at a concentration of 50 mg litre⁻¹. Emission spectra were recorded from 300 to 650 nm and 470 to 650 nm at constant excitation wavelengths of 243 and 455 nm, respectively. Excitation spectra were obtained by scanning from 220 to 480 nm and measuring the radiation emitted at 500 nm. Excitation and emission slits were set at 10 nm bandwidth and the sweep resolution at 0.5 nm, and a scanning speed of 20 nm s⁻¹ was used for both monochromators.

PCA analysis

A window in the range of 270 at –10 p.p.m. (290 experimental points) was selected for the NMR data, and 100 points (variables) were used for EPR and fluorescence spectroscopy. The spectral data (NMR, EPR and fluorescence) of the 12 samples

were centred by subtracting the average value of the samples for each data point. That means that the results can be interpreted in terms of deviations from the average. The PCA was carried out using MATLAB (The MathWorks, Natick, MA, USA) and The Unscrambler (CAMO Software AS, Oslo, Norway) software. In all cases, two components were extracted, capturing at least 90% of the total variance. The model validation was carried out using different methods: full cross-validation, and segmented cross-validation with two and three samples per segment picked at random. The difference in the variance between the calibration and validation models was less than 5%.

Results and discussion

The EPR spectra showed the typical signal of: dipolar interactions between neighbouring Fe^{3+} ions; the signals of organic free radicals; Fe^{3+} in rhombic symmetry sites; Cu^{2+} in axial symmetry; and VO^{2+} in an inner sphere complex with humic acids in a ligand environment consisting mainly of oxygen donors on the equatorial plane of the VO^{2+} complex. Details about EPR analysis and interpretation can be found in Novotny *et al.* (2006).

Regarding $T_{1\rho}\text{H}$, the fitting of spin-lock data and the F -test indicate at least two components, one slow and one rapidly relaxing (Table 1). The O-C groups, from carboxyl and carbohydrates (O-alkyl and di-O-alkyl), show the shorter $T_{1\rho}\text{H}$ values for the rapidly relaxing components, and the proportion of these components correlates with the vanadyl ion contents ($r = 0.99, 0.95$ and 0.97 for carboxyl, di-O-alkyl and O-alkyl, respectively). Correlation analyses, carried out on earlier work (Novotny *et al.*, 2006), have indicated that vanadyl ions have a strong interaction with the O-C groups from carboxyl and carbohydrates (O-alkyl and di-O-alkyl). The present $T_{1\rho}\text{H}$ measurements support the view that this suppression is possibly due to a shortening of $T_{1\rho}\text{H}$ by dipolar interaction. However, the contribution of other mechanisms, such as paramagnetic shift and/or broadening of the resonances (Günther, 1995; Wickramasinghe & Ishii, 2006) cannot be ruled out.

Table 1 Proton rotating frame relaxation times ($T_{1\rho}\text{H}$), average of six selected samples, with standard errors

Functional group	$T_{1\rho}\text{H}/\text{ms}$	
	Slowly relaxing component	Rapidly relaxing components
Carboxyl, amide (156–186 p.p.m.)	4.49 ± 0.18	0.47 ± 0.02
O-aryl (143–156 p.p.m.)	4.82 ± 0.24	0.60 ± 0.02
Aryl (109–143 p.p.m.)	4.89 ± 0.21	0.59 ± 0.04
di-O-alkyl (91–109 p.p.m.)	4.49 ± 0.30	0.46 ± 0.02
O-alkyl (59–91 p.p.m.)	4.07 ± 0.21	0.40 ± 0.03
Methoxyl, N-alkyl (45–59 p.p.m.)	4.57 ± 0.28	0.61 ± 0.03
Alkyl (0–45 p.p.m.)	4.58 ± 0.31	0.62 ± 0.02

The vanadyl ion was present in the range of $20\text{--}60\ \mu\text{g g}^{-1}$ and it may be questioned as to how such a small content can have detectable effects. Additionally, these effects on the NMR signal intensity were not stoichiometric. That could be explained by considering: that each of the VO^{2+} coordination bonds could involve dipolar interaction ($< 1\ \text{nm}$) in altered (e.g. the formation of uronic acids) or fragmented cellulose structures; VO^{2+} coordination would occur in hydrophilic domains, affecting other surrounding groups; based in the $T_{1\rho}\text{H}$ and proton spin diffusion values the selective signal loss, caused by the paramagnetic ion, can affect the groups in the range $2\text{--}30\ \text{nm}$ (Zumbulyadis, 1983; Schilling & Cooper, 2004b); and, the metal coordination could be a cause of a steric rearrangement of the humic acids (Schilling & Cooper, 2004a), and other hydrophilic groups would be moved closer to the binding sites. Additionally, the contents of other paramagnetic ions can be correlated with the VO^{2+} content. In this way, the VO^{2+} ion could be regarded as a probe to indicate the nature of the binding sites. It could be interpreted as a sampling of the ion's population, and a greater content of VO^{2+} ions would indicate a greater content of other paramagnetic ions in similar binding sites. However, EPR was not able to provide a better speciation of these other detectable paramagnetic ions, as was the case for VO^{2+} , because these ions exist also in other forms (e.g. in clusters) (Novotny *et al.*, 2006).

Regarding the PCA, the first principal component (PC1), from the ^{13}C VACP MAS NMR spectra, captured 67% of the total variance. Its spectral regions with greater loadings were those associated with lignin (aryl, O-aryl and methoxyl) and C-alkyl (Figure 1a). The PC2 (25% of the total variance) presents the greatest loadings in the spectral region of groups possibly coordinated to VO^{2+} , such as carboxyl, O-alkyl and di-O-alkyl (Figure 1b). That is confirmed by the strong correlation obtained between the scores of this PC and the VO^{2+} content (Table 2). Other regions with positive loadings were from CH_3 groups ($\sim 19\ \text{p.p.m.}$), rigid $(\text{CH}_2)_n$ groups (peak at $32.8\ \text{p.p.m.}$) and aryl C ($\sim 128\ \text{p.p.m.}$), indicating spatial proximity of these groups to the VO^{2+} binding sites or, in the case of the alkyl region, that some of the hydroxyl and carboxyl groups involved in the VO^{2+} complexation are from compounds like alkanolic acids and alkanols.

Similar results were reported by Schilling & Cooper (2004a) when studying Cu complexation by humic acids. These authors suggested the spatial proximity of aryl and alkyl groups to the binding sites, or that the complexation induces a change in the conformation of the organic structure (pseudochelation).

Because the NMR spectra were normalized (unitary area) before the PCA, to avoid interference from the amount of sample used and pulse imperfections, the decrease in the signal intensity of some groups corresponds to a relative increase in the intensity of the other non-affected C groups. In this way the area sums result in the unitary value. That could explain the negative loadings of PC2 in the regions attributed to chemical groups not affected by VO^{2+} , that is mainly lignin signals (Figure 1b).

Figure 1 Loadings of the principal component (PC) extracted from the ^{13}C VACP MAS NMR spectra: (a) PC1 (66.85% of the total variance); (b) PC2 (24.73% of the total variance).

The scores from PC1 clearly differentiate the humic acid samples according to the distinct treatments (Figure 2). The greatest score was associated with the upper superficial layer (0–5 cm), where tillage was most intense, followed, proportionally, by the 5–10 cm layer. Hence, in areas of intense cultivation there is an apparent accumulation of structures associated with lignin (151, 114 and 56 p.p.m.) and alkyl-C, such as crystalline and non-crystalline poly(methylene) (33 and 30 p.p.m., respectively) and methyl groups (0–27 p.p.m.), indicating that such structures have a greater recalcitrance under these conditions.

The score values of PC1 were similar for the different cultivation systems for the humic acids isolated at depths of 10–20 and 20–30 cm, and the values decreased at lower depths, showing that the effects of tillage on the humic acids are limited to the upper layers. It further reveals that the contribution of structures associated with lignin is small in humic acids from the 20–30 cm layer.

The two PC extracted from the EPR data allow us to conclude that the signal of organic free radicals in humic acids is due at least to two paramagnetic centres (Figure 3a), as VO^{2+} suppressed preferably the low field signal ($g = 2.0042$), repre-

sented by PC1 (Table 2). This can be interpreted as evidence for strong interaction between VO^{2+} and the organic free radicals whose resonance signal give a greater g -factor. This can be explained by the nature of these radicals, because an increase in the electron density of an unpaired electron over oxygen atoms gives rise to an increase in the g -factor in organic free radicals (Parish, 1990).

The loadings of PC2 (25% of the total variance) had a g -factor of 2.0029, indicating a free radical centre in which the unpaired electron is delocalised over the carbon backbone, probably in aromatic condensed structures, and its scores confirmed the trend for humification (data not shown) as demonstrated by the scores from the ^{13}C NMR.

In the case of the fluorescence spectra, PC1 captured at least 97% of the total variance in all acquisition modes, and the scores of this PC had a strong correlation with the VO^{2+} contents.

Table 2 Captured variance and correlation with the VO^{2+} content of the PC attributed to the effect of this ion

Spectroscopy		Captured variance/%	Correlation with VO^{2+} ion
Fluorescence	Emission ($\lambda_{\text{ex}} = 243 \text{ nm}$)	99.98	−0.92
	Emission ($\lambda_{\text{ex}} = 455 \text{ nm}$)	99.81	−0.93
	Excitation ($\lambda_{\text{em}} = 500 \text{ nm}$)	97.36	−0.95
	^{13}C -RMN	24.73	−0.95
	Organic free radicals	64.61	−0.88

Figure 2 Scores of the PC1 (66.85% of the total variance) extracted from the ^{13}C VACP MAS NMR spectra.

Figure 3 Loadings of: (a) two PC from EPR data; (b) PC2 of fluorescence data. Emission with excitation at 243 nm (0.16% of the total variance); emission with excitation at 455 nm (0.02% of the total variance); emission with excitation at 500 nm (2.57% of the total variance).

Practically all the observed variance was due to the effect of this ion (Table 2).

The loadings of PC2 in the fluorescence data present a red shift, e.g. positive loadings to longer wavelengths and negative loadings to shorter wavelengths (Figure 3b). This red shift is a typical characteristic of humic substances with large degrees of humification (Senesi, 1990a; Piana & Zahir, 2000). Consequently, these PC might be associated with the degree of humification; the greater the scores the greater the humification.

The scores of PC2 extracted from excitation spectra with emission at 500 nm indicated that increasing the tillage intensity generated more humified humic acids in the 0–5 cm layer. Humic acid samples from the 20–30 cm layer presented a lesser degree of humification (data not shown), in accordance with the results of the PCA from NMR and EPR data.

Conclusions

The VO^{2+} ion affected the spectroscopy results obtained by different techniques (EPR, NMR, and fluorescence) in such a way that a straightforward interpretation of the results has to be made with care because a considerable part of the observed variability did not derive from intrinsic characteristics of the humic acid samples, such as the degree of humification. As a consequence, multivariate techniques were applied to isolate the VO^{2+} ion effect and to obtain new independent variables from it. These new variables were used to estimate the degree of humification and to evaluate the effects of cultivation on humic acids.

Where the most intense soil cultivation was practised, more humified humic acids were obtained, mainly in the upper layers (down to 10 cm), as indicated by the fluorescence and EPR data.

Greater contents, in the humic acids, of recalcitrant structures associated with lignin and long-chain alkyl-C were related to greater humification. We found also that the organic free radicals of the humic acids were attributable to two distinct paramagnetic centres. The VO^{2+} ion suppressed preferentially the signal with the greater g -factor, attributed to organic free radicals with a greater electron density in which the unpaired electron is located over oxygen atoms compared with the unaffected signal whose unpaired electron is delocalised, probably over conjugated C atoms.
