# SCIENTIFIC COUNCIL MEETING - JUNE 2004 

A Survey-based Assessment of Cod in Division 3M<br>by<br>Santiago Cerviño and Antonio Vázquez<br>Instituto de Investigaciones Marinas<br>Eduardo Cabello 6, 36208 Vigo, Spain<br>E-mail: santi@iim.csic.es; avazquez@iim.csic.es

#### Abstract

The cod stock in NAFO Division 3M is in moratorium since 2000. The low catches collected since then make difficult to apply a VPA based assessment to evaluate the current stock status. Hereby, a survey-based assessment method was used to evaluate the present status in a stochastic way; a method that takes into account uncertainties in survey sampling as well as in catchability estimates. The results show that the spawning stock biomass is at the lowest observed level of the survey's series (1988 to 2003) and all its stochastic estimates are under $\mathrm{B}_{\mathrm{lim}}$. Current abundance at age of pre-mature year-classes are also at very low levels and, consequently, a recovery of the stock is not expected in a sort or medium term.

## Introduction

Historical catches are shown in Table 1, where decline of the fishery is clearly observed.
A VPA based assessment of the cod stock in Flemish Cap was approved in 1999 by the first time. In that assessment, the stock status was qualified as collapsed, which was attributed to three possible causes: a stock decline due to overfishing, an increase in catchability at low abundance levels, and a very poor recruitment since 1995. The 2002 last assessment concluded that both total biomass and SSB were at such low levels that the stock would be unable to produce good recruitments in most recent years. Consequently, the recovery of the stock was not expected in a short or medium term time period (Vázquez and Cerviño, 2002).

Since 1974, when a TAC was established for the first time, catches ranged from 48,000 tons in 1989 to a minimum of 37 tons estimated for 2000. Annual catches were about 30,000 tons in the late-1980's, when the fishery was under moratoria, and they decline since then as a consequence of the stock collapse. Since 1997 catches were less than 1,000 tons and since 2000 they were less than 100 tons, mainly attributed to by-catches of Spanish and Portuguese fleets in the area.

The former 1999 VPA based assessment was annually updated until 2002. However, most recent catches were small, under 100 tons, and VPA based assessment are quite sensitive to natural mortality (M) values when catches are at low levels, as in this case. The F estimates from last analysis were at the same level than M in both 1998 and 1999 and lower than M in 2000 and 2001 (Vázquez and Cerviño, 2002). XSA results are not reliable under these conditions.

A $B_{\text {lim }}$ of 14,000 tons was established in 2001 (Cerviño and Vázquez, 2000), and it remains as the only reference point accepted for this stock. Given the present moratorium, the fishery re-opening criterion may include a decision on the current SSB estimates being above that level in probabilistic terms. The survey-based assessment proposed here is similar to the method described by Cerviño and Vázquez (2003). It combines survey abundance indices at age with the estimated catchability at age from recent XSA. Indices and catchability uncertainty are used to calculate the statistical distribution of SSB estimates and its probability of being above $\mathrm{B}_{\text {lim }}$.

## Material and Methods

## Data

Data needed to estimate SSB probability distribution are: indices of abundance at age and their errors; survey catchability at age and their errors; weight at age and maturity at age percentages. Errors in these last two variables were not taken into account. An estimate of total mortality is also needed to transform the abundance at survey time (in summer) to the beginning of the year.

The EU bottom trawl survey of Flemish Cap was carried out since 1988 targeting the main commercial species inside the 730 meters bathymetric contour. The surveyed zone includes the complete area distribution for cod, which rarely occurs deeper than 500 meters. The sampling procedure did not change along the series, although the research vessel used in 1989, 1990 and 2003 was not the same as used for the rest of the series. Sampling of main species includes age, length, weight and maturity. The 2003 survey was carried out with the new R/V Vizconde de Eza (Casas et al., 2004) keeping the same gear and survey procedure. A comparative fishing trial with the R/V Cornide the Saavedra was performed in 2003, but the 60 paired hauls were not considered enough for calibration given the low cod abundance. The trial will be continued in 2004. The 2003 survey results for cod are used without transformation for this paper. Estimates of cod abundance at age, their standard errors and their auto-correlations were calculated following Cerviño (2002) and they are presented in Table 2; weight and maturity at age are presented in Table 3.

Catchability at age was derived from a XSA based on catch data until 1999. Annual catches after 1999 are too low and they introduce more uncertainty on XSA results. Age 1 was calibrated with a two-parameters model. Catchability for ages 2, 3 and 4 were estimated from a one-parameter model, and catchability for older ages was considered constant and equal to age 4 catchability. Variance of catchability estimates from XSA has two components: one due to the survey sampling variability and other due to the year to year catchability variability. A bootstrap-subtracting algorithm based on the XSA model was defined to quantify the second component, assuming additivity and independence among both components. The algorithm has three steeps:

1. Total error in catchability parameters is estimated by conditioned bootstrap. Covariance matrix is presented in Table 4 (upper panel).
2. Partial errors due to indices variability are estimated by unconditioned bootstrap. Covariance matrix is presented in Table 4 (intermediate panel)
3. Catchability covariance matrix is calculated by subtracting the two previous matrices: the one due to survey variability from the one due to total variability. The result is presented in Table 4 (lower panel)

Catchability used for simulation: values, standard errors and correlation matrix, is presented in Table 5.

## The stochastic model

The model follows the catchability equation, which relates the true abundance ( N ) with an abundance index (I):

$$
I_{y, a}=q_{a} * N_{y, a} * \varepsilon
$$

where $q$ is the catchability and $\varepsilon$ an error factor; the sub-index $y$ relates to the year and $a$ to age. Based on that, $N$ is estimated from abundance index and estimated catchability according to:

$$
N_{y, a}=I_{y, a}^{*} / q_{a}^{*}
$$

where the super-index * indicates stochastic values. $I$ and $q$ are assumed to follow a lognormal distribution with expected value and standard errors as described before. $Q$ covariances were included in the model, but $I$ covariances were not included because they are low in the last years.

The abundance ( $N$ ) needs to be corrected to the beginning of the year $\left(N^{0}\right)$ because that is the scale for $\mathrm{B}_{\mathrm{lim}}$. Since the UE survey is carried out in the middle of the year, the assumed total mortality $(Z)$ included natural mortality ( $M$ ) equal 0.2 , and fishing mortality $(F)$ from 2002 assessment, which was considered negligible.

$$
N_{y, a}^{0}=N_{y, a} * \exp \left(t^{*} Z\right)
$$

SSB was calculated from survey results as the sum of products of abundance at age ( $N$ ), mean weight ( $W$ ) and maturity rate (Mat) at age.

$$
S S B=\sum_{a=1}^{n} N_{y, a}^{0} * W_{y, a} * M a t_{y, a}
$$

SSB distribution was calculated by a bootstrap where $I$ and $q$ were re-sampled independently 2000 times. The method allows estimating the bootstrap statistical properties of abundance at age and SSB: mean, standard deviation, coefficient of variance, skewness, statistical bias and percentiles.

## Results

Deterministic results for abundance at age and for SSB are presented in Table 6. Abundances at age in that table were estimated independently for each year from survey results and do not follow any SPA results; it implies that cohort abundances are not forced to decrease year to year necessarily. The 2003 SSB are at the lowest observed level, 846 tons, well below the figure for all other years in the series. Abundance at ages 2 to $8+$ in 2003 are at the lowest observed level; recruitment at age 1 in 2003 is the highest since 1995, however it remains at a low level in relation to the abundance in years before 1995.

Results are presented in Tables 7 and 8, and in Figures 1 and 2. Table 7 shows the bootstrap statistics for abundance at age. All the means are lightly above their deterministic values due to bias in the range between $0.8 \%$ and $1.8 \%$, except for age 1 , which had a bias of $50.2 \%$. Abundance at age 1 was estimated with the two parameters model and it is likely that its distribution doesn't match properly to the assumed lognormal distribution. Coefficient of variance ranges from 1.29 for age 7 to 0.18 for age 3 . All values have positive skewness.

SSB estimates are showed in Table 8. Their means are also lightly over their deterministic values, and their bias are about $1.5 \%$ in the whole series. Coefficients of variance range from 0.15 in 1990 to 0.26 in 1992, being 0.24 in 2003. All the skewness are positive. Figure 1 shows the trend in SSB with the $90 \%$ percentiles as well as the values derived from last XSA (Vázquez and Cerviño, 2002). Although XSA values are in some cases outside the confidence margins of survey-based values, both series show similar trends and both XSA and survey-based SSB are under $\mathrm{B}_{\mathrm{lim}}$ since 1996. Figure 2 shows the most important result for reopening fishery advice: the cumulative SSB distribution that shows the probability of being over $\mathrm{B}_{\text {lim }}$ which is 14,000 tons for 3 M cod. Any of the 2000 bootstrap values are below $\mathrm{B}_{\mathrm{lim}}$.

## Discussion

The observed trends of the EU bottom trawl survey abundance at age are clear enough to realize that 3M cod stock continues collapsed. All year-classes are at similar or lower level than in previous years, and no signal of recovery is observed. The abundance at age 1 in the EU survey in 2003 is the highest observed since 1996, nevertheless it is far away from the values observed before 1996, and it is not expected a recover the stock based on the observed low level of all cohorts.

The proposed survey-based method doesn't modified the survey perception about the current stock status, nevertheless it has other advantages, particularly when, thinking in a future stock recovery, the Scientific Council has to advise about re-opening the fishery and the risk associated with that decision.

- The method avoids the use of a VPA based method, which results became unrealistic year after year given the low catch levels that occurred since 2000.
- The method uses abundance indices and catchability at age from SPA as input variables to produce an absolute SSB estimate, the same scale used to set $\mathrm{B}_{\mathrm{lim}}(14,000$ tons for $3 \mathrm{M} \operatorname{cod})$.
- The method provides the error distribution of state variables, SSB and abundance at age, taking into account the survey sampling errors and the survey catchability errors.
- The method provides the distribution SSB estimates, which allows calculating the probability of being above $B_{\text {lim }}$, avoiding the need of setting $B_{\text {buff }}$ as a precautionary decision reference.
- The abundance at age distribution allows the use of stochastic projections as a tool to advise on the fishing mortality that could be applied after re-opening.
- The method can be applied to other stocks in a situation similar to Flemish Cap cod. A survey with estimated errors of abundance at age and estimates of catchability at age are only needed.

In summary, the current SSB, being estimated as 846 tons, is at its lowest observed level in the whole series and, although recruitment at age 1 shows a lightly increase respect to previous years, this is not enough to expect a stock recovery in a short or medium term.
