Abstract

A mechanochemical procedure is proposed for an easy preparation of a BaTiO₃-Ni composite in a single steep. BaTiO₃ and Ni powders available in the market are mixed by dry ball milling producing a decrease of particle size and an evenly distribution of both phases. In the sintered pellets the nickel particles are homogeneously distributed into the BaTiO₃ matrix and isolated from others Ni particles. The dielectric constant of the composite is considerably higher than that of the barium titanate. Moreover, the temperature of the ferroelectric ↔ paraelectric transition of the BaTiO₃-Ni composite here prepared is much lower than the one of the pure BaTiO₃ single phase.

Introduction

Ferroelectric ceramics are widely used in a broad range of applications, especially in the design of electronic devices such as capacitors, dielectrics or electroactive materials [1-3]. Barium titanate (BaTiO_3) is one of the most used ferroelectric ceramic in electronics due to its high dielectric constant, which makes it a very attractive material to use in capacitors such as boundary layer capacitors (BLC) and multilayer ceramic capacitors (MLCC) [3-5]. Because of its extensive use, it has been widely studied and several methods have been proposed to enhance its dielectric constant. Thus, it has been observed that the homogeneous dispersion of an electrically conductive filler, such as small metal particles, into an insulating matrix leads to an increase in the dielectric constant of the composite [3, 6]. This raise reaches its maximum in the neighbourhood of the percolation threshold, where the dielectric constant experiments an abrupt increase [7-9]. As the metal content grows over the percolation threshold, an insulator-conductor transition is recorded and both conductivity and permittivity increase [10, 11]. This phenomenon may be explained by the isolation of the metal particles by thin dielectric layers near the percolation threshold. Hence the composite turns into a capacitor with good charge storage properties. This behaviour is well known and it has been explained by the percolation theory [12]. Moreover, it has been observed that the incorporation of metal particles improve the sintering process, because metal particles undergo plastic deformation and thereby relax the internal stresses induced during the sintering [3, 13-17].

These kind of insulator/conductor composites have been intensely investigated in the last years [3, 18-21] and present a great scientific and engineering interest. Recently, Pecharroman *et al* [22] have designed a BaTiO_3 -Ni composite with an

1 extremely high dielectric constant. In a similar way, Chen *et al* [3] reported the
2 enhancement of the dielectric properties of X7R barium titanate ceramic by addition of
3
4 nickel nanoparticles, while Qiao and Bi observed an improvement in the dielectric
5
6 behaviour of BaTiO₃-Ni composite ferroic film. Lin *et al* [23] registered an analogue
7
8 behaviour when incorporating silver particles to an NBT ceramic matrix, Panteny *et al*
9
10 in barium titanate-silver composite [11] and George *et al* in barium samarium titanate-
11
12 silver composite [10].
13
14
15

16
17 The most common method of preparing these metal-ceramic composites is
18
19 colloidal processing, which implies using nanoparticles of both constituents and high
20
21 volumes of water [7, 22]. Other methods involves using co-sputtering methods[24] or
22
23 wet grinding [10]. In this work we propose the preparation BaTiO₃-Ni nanocomposites
24
25 by dry grinding stating form conventional powders. Additionally, the dielectric
26
27 behaviour of BaTiO₃-Ni nanocomposite prepared are investigated.

38
39
40

41 The composites were prepared from commercial Ni (Sigma-Aldrich 266981-
42
43 500G, 3µm, 99.7 % in purity) and BaTiO₃ (Aldrich 12047-27-7, 2µm, 99.9 % in purity)
44
45 samples. Powder mixtures containing 28 vol % nickel and 72 vol % BaTiO₃ were
46
47 placed in a agate jar (300 cc volumen) with 12 agate balls 20 mm in diameter and
48
49 milled using a centrifuge mill (model Fritsch Pulverisette) at 730 r.p.m. Different
50
51 milling times were used for comparison. The surface areas of all powders were
52
53 determined with a surface area analyzer (model FlowSorb III 2310, Micrometrics
54
55 Instruments), using N₂ as an adsorbate at the liquid nitrogen temperature. Size

1 measurements were also made by light scattering procedure by means of a particle size
2 analyzer (model Mastersizer, Malvern)
3

4 Ball milled powders were pressed into discs of 13 mm in diameter and 1 mm in
5 thickness by uniaxial pressing at 860 MPa. Then, the discs were sinterized at 1300°C
6 under N₂ atmosphere for 2 hours using a Carbolite 1500°C horizontal tube furnace. The
7 densities of all discs were determined both before and after sintering using the
8 Archimedes method.
9

10 Dilatometric curves for pure BaTiO₃ and for BaTiO₃-Ni composite under
11 nitrogen atmosphere were obtained with a home-made dilatometer that measures the
12 thickness change with temperature during the sintering process.
13

14 The microstructures of both powders and sintered discs were studied by
15 scanning electron microscopy (SEM)) in a Jeol instrument equipped with energy
16 dispersive x-ray spectrometer (EDX).
17

18 X-ray powder diffraction patterns were obtained with a Siemens D501
19 instrument using CuK_α radiation and a graphite monochromator. The full-width of the
20 half-maximum (FWHM) of (111) diffraction peak was used for calculating the
21 coherently diffracting domain for both Nickel and BaTiO₃ particles, according to the
22 Scherrer equation.
23

24 The sintered discs were placed between two platinum electrodes for measuring
25 their dielectric constant and the dielectric loss by means of a LCR meter (IET, model
26 IMF 600A). The two parallel surfaces of the sintered discs were covered with gold by
27 means of a sputtering device for improving the electrical contact with the platinum
28 electrodes.. The temperature dependences of the dielectric constant and dielectric loss
29 were measured at temperatures ranging from 25°C to 200°C at 1 KHz.

Results and discussion

Fig. 1 shows the XRD patterns corresponding to a starting barium titanate and nickel mixture before milling (Fig. 1a) and to a BaTiO₃-Ni powder milled for one (Fig. 1b), four (Fig. 1c) and eight hours (Fig. 1d). Both phases, Ni and BaTiO₃, remain crystalline after grinding treatment, but diffraction peaks becomes broader with the treatment due to a decrease in crystallite size. Thus, the crystallite size decreases for the starting powders from 117.0 and 136.3 nm for the BaTiO₃ and Ni, respectively, to about 45.5 and 63.8 nm for the BaTiO₃ and Ni, respectively, after grinding for one hour (Table 1). As grinding time proceeds, crystalline sizes decrease, yielding a minimum value of 28.4 and 30.3 nm for the BaTiO₃ and Ni, respectively, after eight hours treatment. The BET specific surface values obtained for the different milled samples are presented in Fig. 2. The specific surface value quickly rises with the grinding time, from about 1.2 m² g⁻¹ for the unmilled sample to a maximum value of 11.6 m² g⁻¹ for the sample ground for four hours. After 4 hours of milling, the specific surface start to decrease until reaching a stade state value of 7.4 m² g⁻¹ from 8 hours of treatment. Thus, these results indicate that although the crystallite size decreases with the grinding time in entire studied range, surface area reaches a maximum at a 4-hour of milling time, and starts decreasing thereafter, probably due to aggregation produced by the grinding procedure.

Fig. 3 shows the scanning electron micrographs of starting nickel and barium titanate powders (Figs. 1a and 1b, respectively) and BaTiO₃-Ni powder milled for 4 hours (Fig. 1c). Original powders consist of irregular and micron-sized particles highly aggregated. It can be appreciated that composite particles are also highly aggregated, although the subunits are smaller than in the starting powders. The micrograph of milled

sample also reveals that nickel and BaTiO₃ particles presents a very homogeneous distribution, which is proved by the EDX mapping made for further confirmation, and presented in Fig. 1d.

Fig. 4 shows the particle size distribution curves as obtained by light scattering procedure for the starting powders and the composite. As shown in the figure, both BaTiO₃ and Ni starting powders have a broad particle size distribution with modal sizes at 2.65 μm and 7.35 μm for BaTiO₃ and Ni, respectively. For the mixture ball-milled for four hours, the modal size decreases to 1.41 μm , but the curve shows a very broad particle size distribution because of the high degree of aggregation of the small particles, as also observed in the SEM micrograph (Fig. 3. c).

Fig. 5 shows the dilatometric curves obtained for both pure BaTiO₃ and BaTiO₃-Ni sample milled for four hours. Both dilatometric curves are quite similar except for a slight shift to lower temperatures for the BaTiO₃-Ni composite due to the inclusion of metal particles in the barium titanate matrix, which promotes the sintering process. This behaviour could be understood in terms of a plastic deformation of the metallic particles that relax the internal stresses that occurs during the sintering [3, 13-17]. The dilatometric curve shows that sintering is complete at 1300°C, therefore, composite pellets were prepared from the BaTiO₃-Ni powder milled during 4 hours by sintering the pressed powders at 1300°C under N₂ atmosphere for 2 hours. The density of the pellets thus obtained was measured by the Archimedes method, yielding a final densification of 98%. In Fig. 6 a scanning electron micrograph taken from the surface of the sintered sample is presented, as well as a Ni and Ti mapping image, showing an evenly dispersion of nickel particles into the BaTiO₃ matrix. Thus, nickel particles are surrounded by the BaTiO₃ phase and isolated from other Ni particles, indicating that the system has not overpassed the percolation threshold.

Fig. 7 shows the dependence of the dielectric constant and the dielectric loss of the composites on the temperature. It is noteworthy the significant effect the inclusion of metal particles have on the dielectric behaviour of the BaTiO₃. The dielectric constant of the BaTiO₃-Ni is much higher than that of the pure BaTiO₃ in the entire range of temperature studied, while the maximum values for both pure BaTiO₃ and BaTiO₃-Ni are 470 and 10850, respectively. Additionally, the maximum of the dielectric constant that occurs at 122-125°C [25-30] in BaTiO₃ and is associated to a ferroelectric (tetragonal) to paraelectric (cubic) phase transition is moved down to 82°C in the BaTiO₃-Ni nanocomposite. Moreover, the very low dielectric loss of this composite (about 0.04) supports the high quality of the dielectric here prepared.

Conclusions

An easy and rapid method for obtaining BaTiO₃-Ni nanocomposites by mechanical grinding has been developed. This method allows working with conventional starting powders, because the milling itself reduces particle size at the same time that the components get thoroughly dispersed, thus obtaining a homogeneous nanocomposite by a simple procedure in a single step. The incorporation of metal nickel particles into a barium titanate matrix results in an improvement of the electric properties over the pure ferroelectric matrix. The high dielectric constant presented by the nanocomposite and the simple preparation procedure makes it an attractive material for different technological applications.
