ABSTRACT

This paper presents a software tool that enables the identification and automated tracking of oceanic eddies observed with satellite altimetry in user-specified regions throughout the global ocean. As input, the code requires sequential maps of sea level anomalies such as those provided by Archiving, Validation, and Interpretation of Satellite Oceanographic (AVISO) data. Outputs take the form of (i) data files containing eddy properties, including position, radius, amplitude, and azimuthal (geostrophic) speed; and (ii) sequential image maps showing sea surface height maps with active eddy centers and tracks overlaid. The results given are from a demonstration in the Canary Basin region of the northeast Atlantic and are comparable with a published global eddy track database. Some discrepancies between the two datasets include eddy radius magnitude, and the distributions of eddy births and deaths. The discrepancies may be related to differences in the eddy identification methods, and also possibly to differences in the smoothing of the sea surface height maps. The code is written in Python and is made freely available under a GNU license (<http://www.imedeia.uib.es/users/emason/py-eddy-tracker/>).

1. Introduction

Satellite altimetry has revealed the ubiquity of mesoscale eddies in the global ocean (e.g., Stammer 1997, 1998). Eddies range greatly in shape and size, are often asymmetric, and can have highly variable translational and rotational velocities (McWilliams 2008; Chelton et al. 2011b, hereafter CSS11; Early et al. 2011). Interest in mesoscale eddies arises from their role in the dynamics of the large-scale oceanic circulation; eddies are efficient carriers of mass and its physical, chemical, and biological properties, such that their presence modulates fluxes of heat and momentum and the dynamics of marine ecosystems (Chelton et al. 2011a; Gruber et al. 2011; Stramma et al. 2013).

Recent years have seen the emergence of several automated oceanic eddy tracking algorithms that contribute to knowledge of eddy properties and their variability. The techniques comprise three main methods: geometric (e.g.,

Chaigneau et al. 2008; Nencioli et al. 2010; CSS11); Okubo–Weiss (e.g., Isern-Fontanet et al. 2003; Morrow et al. 2004; Chelton et al. 2007; Ubelmann and Fu 2011); and wavelet (e.g., Doglioli et al. 2007; Rubio et al. 2009); and a comparative analysis of these approaches has been made by Souza et al. (2011). Novel techniques falling outside these methods are a hybrid geometric Okubo–Weiss approach (Halo et al. 2014), and an objective approach based on geodesic transport theory (Beron-Vera et al. 2013).

Two decades' worth of merged global sea surface height (SSH) from multiple satelliteborne altimeters are presently available from Archiving, Validation, and Interpretation of Satellite Oceanographic (AVISO) data, providing improved resolution of mesoscale features and their variability (Pascual et al. 2006). CSS11 applied an SSH anomaly–based eddy tracking algorithm to these data for the period 1992 to (at time of writing) 2012, and they make available a periodically updated database of the tracks and associated properties on their website.

In this article we evaluate and release a new SSH-based eddy tracking code that demonstrates comparable results to the CSS11 data. By providing code rather than

FIG. 1. (a) High-pass-filtered AVISO sea level anomaly (cm) over the py-eddy-tracker eddy tracking domain (11.5° – 38.5° N, 65° – 5.5° W) on 28 Aug 1996 (cf. Fig. 1 of CSS11). The locations of currently active eddies with lifetimes greater than 4 weeks are marked by blue (red) dots for cyclones (anticyclones); lines marking the paths of the eddies since birth show that most eddies track westward. The analysis domain studied in section 3 is indicated by the gray rectangle; the Canary Islands are located near the top-right corner. (b) Graphical illustration of relationships between effective and speed-based contours used for eddy identification, and the coordinates available for eddy tracking. Contour C_{eff} in red is the outline of an irregularly shaped cyclonic eddy that is plotted over a corresponding map of the geostrophic velocity U_g . The eddy has been identified by py-eddy-tracker; its location marked by the black box in (a). The point P_{eff} is the centroid of C_{eff} , and a circle with the same area as C_{eff} is shown by $\odot P_{\text{eff}}$; the corresponding shape error is 49%. The equivalent speed-based approximation of the eddy is described by C_{spd} , P_{spd} , and $\odot P_{\text{spd}}$ in green; the shape error is now reduced to 24%. Red and green arrows with origins at P_{eff} and P_{spd} show the radius scales L_{eff} and L_{spd} , respectively. The black interior contour, C_{trk} , corresponds to the pixel count limit $I \rightarrow I_{\text{min}}$; py-eddy-tracker utilizes the centroid of this contour, P_{trk} , for eddy tracking. Gray contours show the remaining contours that are sampled in order to identify C_{spd} and, hence, estimate L_{spd} .

a database, users may (i) track eddies using the most recent AVISO data, and (ii) adapt the code to specific regions and/or different data sources, such as oceanic numerical model outputs. The code is written in Python (e.g., Hunter 2007; Oliphant 2007); details of the algorithm are presented in section 2. The eddy tracker (py-eddy-tracker) is applied in section 3 to the region of the Canary Eddy Corridor (CEC; Sangrà et al. 2009) off the northwestern African coast. Comparisons with two other regions, the South Atlantic Ocean (SAO; Souza et al. 2011) and southeast Pacific (SEP; Chelton et al. 2011a), are summarized in tabular form. A discussion of some of the differences with CSS11 is provided in section 4, followed by brief conclusions in section 5.

2. Methodology

The py-eddy-tracker SSH-based approach is loosely based on procedures described by CSS11, Kurian et al. (2011), and Penven et al. (2005). Input sea level anomalies (SLA) are the same gridded weekly delayed-time global reference data from AVISO (e.g., AVISO 2013) as used by CSS11.

a. Eddy identification

Individual SLA fields are spatially high-pass filtered by removing a smoothed field obtained from a Gaussian filter with a zonal (meridional) major (minor) radius of 10° (5°). An example filtered global SLA map on 28 August 1996 (not shown) makes good visual comparison with the high-pass filtered SLA field presented by CSS11 (their Fig. 1, bottom), although we are unable to make a quantitative comparison. The code works with interpolated contours of smoothed SLA; this is analogous to Kurian et al. (2011) but distinct from CSS11, who use raw SLA pixels. The impacts of any differences between ours and CSS11's results that may arise from the respective smoothing and contour handling procedures (henceforth inherent differences) are difficult to assess.

The eddy identification process requires specification of a tracking domain; the CEC tracking domain is shown in Fig. 1a. From a subset of the global SLA corresponding to the tracking domain, SLA contours are computed at 1-cm intervals for levels -100 to 100 cm. To identify cyclones (CC) [anticyclones (AC)], the contours are searched from 100 (-100) cm downward (upward). At

each SLA interval, closed contours (C_C) are sequentially identified and analyzed; for selection as a potential eddy, a C_C must meet a series of criteria relating to its shape and interior characteristics:

- (i) Pass a shape test with error $\leq 55\%$, where the error is defined as the ratio between the areal sum of C_C deviations from its fitted circle and the area of that circle (see Fig. 1b; Kurian et al. 2011).
- (ii) Contain a pixel count, I , satisfying $I_{\min} \leq I \leq I_{\max}$, where $I_{\min} = 8$ and $I_{\max} = 1000$.
- (iii) Contain only pixels with SLA values above (below) the current SLA interval value for anticyclonic (cyclonic) eddies.
- (iv) Contain no more than one local SLA maximum (minimum) for an anticyclone (cyclone). This constraint differs from CSS11, who permit multiple local maxima/minima; see section 4 for a comment on the potential implications of this difference.
- (v) Have amplitude (A) that satisfies $1 \leq A \leq 150$ cm.

The above criteria, barring the shape test and local minima/maxima threshold, are identical to CSS11 (see their section B3).

When a C_C passes the above-mentioned tests, it is identified as an eddy and, henceforth, is referred to as the effective perimeter of the eddy (C_{eff}). Following CSS11, an associated effective radius (L_{eff}) is defined as the radius of a circle with the same area as the region enclosed by C_{eff} . These features are illustrated in red in Fig. 1b; the centroid of C_{eff} is denoted by P_{eff} and the same-area circle by $\odot P_{\text{eff}}$. Next, a speed-based eddy radius (L_{spd}) is found, defined as the radius of the circle with the same area as the region within the C_C of SLA with maximum average geostrophic speed (U , the rotational speed of the eddy). Eddy radius L_{spd} is estimated by iterating from C_{eff} inward over all C_C s whose pixel count satisfies $I_{\min} \leq I \leq I_{\max}$; L_{spd} and its associated contour, C_{spd} , are shown in green in Fig. 1b. The tracking centroid (P_{trk}) in black in Fig. 1b corresponds to the contour of the last iteration (C_{trk} , where $I \rightarrow I_{\min}$).

Finally, SLA pixels corresponding to the eddy are masked, making the region unavailable for further eddy identification. Figure 1a shows the positions of eddies identified following the above-mentioned procedures within the CEC tracking domain on 28 August 1996.

b. Eddy tracking

Eddy tracking is accomplished using positions P_{trk} , in contrast to CSS11, who use P_{eff} (Fig. 1b). We choose P_{trk} rather than P_{eff} (or P_{spd}) because, while in most instances the three coordinates are closely located, sometimes they are not. In these cases, tracking with P_{eff}

or P_{spd} occasionally resulted in spuriously dropped tracks; this behavior was improved by using P_{trk} .

Cyclones and anticyclones are treated separately. Separation distances between all identified P_{trk} positions at time steps k and $k + 1$ are computed. Assignment of $k + 1$ candidates to k active eddies is decided using the ellipse method of CSS11. If multiple $k + 1$ eddies fall within the ellipse, then the eddy is assigned according to the minimum of a set of dimensionless similarity parameters, S (Penven et al. 2005), that are computed for each $k + 1$ candidate:

$$S_{k,k+1} = \sqrt{\left(\frac{\Delta d}{d_0}\right)^2 + \left(\frac{\Delta a}{a_0}\right)^2 + \left(\frac{\Delta A}{A_0}\right)^2}, \quad (1)$$

where Δd is the separation distance between eddies at times k and $k + 1$, Δa is the variation of eddy area (based on L_{spd}), and ΔA is the variation of amplitude. Characteristic values for eddy separation distance, area, and amplitude are given by, respectively, d_0 , a_0 , and A_0 . We use the same values, namely, $d_0 = 25$ km (based on the AVISO time scale of one week), $a_0 = \pi 60^2$ km², and $A_0 = 2$ cm, in all the experiments presented in section 3.

Unused $k + 1$ eddies are considered to be new eddies. The coordinates P_{trk} and parameters L_{eff} , L_{spd} , A , and U of eddies with lifetimes greater than a threshold minimum number of days are stored; examples of 28-day minimum eddy tracks (the same threshold is applied to the CSS11 data in section 3) are shown in Fig. 1a. The eddy tracking process continues by iteration over the temporal tracking domain.

3. Applications

To demonstrate the performance of py-eddy-tracker, we apply the algorithm to three distinct tracking domains: the CEC, SAO, and SEP. The runs cover the same 14 October 1992–4 April 2012 time period. Annual climatologies of eddy density (all observations, and also birth and death locations) and polarity are computed, as well as histograms of eddy lifetimes, radii, and amplitudes. Identical figures prepared from the CSS11 dataset are included for comparison. Figures are shown only for the CEC analysis domain, outlined in gray in Fig. 1a. Statistics from all three analysis domains are shown in tabular form.

Figure 2 compares spatial patterns of CEC anticyclone and cyclone density (eddy numbers per 1° square per year) and polarity from py-eddy-tracker and CSS11. Overall, good qualitative and quantitative agreement is found. Both methods identify elevated mesoscale activity associated with the Canary Islands (CI; Barton

FIG. 2. Contour plots of Canary Eddy Corridor mean eddy counts per 1° square per year and eddy polarity from (top) py-eddy-tracker and (bottom) CSS11, and (left) anticyclone counts (n_a), (middle) cyclone counts (n_c), and (right) polarity $[(n_c - n_a)/(n_c + n_a)]$. Regions in the polarity maps where either $n_c < 0.25$ or $n_a < 0.25$ are masked.

et al. 2004). The 95% confidence intervals from Student's t tests along 26°N are approximately two eddy counts wide (not shown), indicating that the higher counts near the CI are real. The polarity maps also display closely matching patterns. Anticyclone dominance is strong along the upwelling and is also significant along a wide zonal band at $\sim 25^\circ\text{N}$. Pearson correlation coefficients (r) between the respective datasets are positive and large for both eddy signs ($r > 0.8$), although slightly smaller for polarity (Table 1).

Figure 3 presents eddy statistics from the two datasets. The annual mean numbers of eddies with lifetimes between 4 and ~ 25 weeks are similar (Fig. 3a); py-eddy-tracker eddies are slightly more numerous at 20 weeks and less. More than ~ 30 weeks, the eddy count is mostly fewer than 10 eddies per year. The py-eddy-tracker records one or two cyclones with lifetimes exceeding 60 weeks; CSS11, however, find cyclones with ages greater than 100 weeks. Cyclones are generally dominant in both datasets (Fig. 3b).

Histograms of eddy radii (L_{spd}) from CSS11 and py-eddy-tracker in Fig. 3c show some differences. CSS11 find a wider distribution of radii, with a peak of ~ 40 eddies per year at $L_{\text{spd}} \approx 75$ km; the py-eddy-tracker data have a tendency for more and smaller eddies, with a peak of ~ 55 eddies per year at $L_{\text{spd}} \approx 65$ km. Explanations for these differences are explored in section 4. Both datasets show anticyclonic (cyclonic) dominance at smaller (larger) scales (Fig. 3d). Figures 3e,f reveal close

agreement in the distribution and polarity of eddy amplitudes between the two datasets. There is also good agreement in eddy nonlinearity¹ although py-eddy-tracker tends to predict slightly more nonlinear eddies (Figs. 3g,h).

Scatterplots of eddy radius versus amplitude for cyclones and anticyclones from the two datasets are shown in Figs. 3i,j. There is good general agreement between the datasets in the distributions for both eddy signs; however, a marked difference in the magnitude of the radii is visible at smaller amplitudes.

Annual mean CEC eddy birth and death location densities from py-eddy-tracker and CSS11 are compared in Fig. 4. The density distributions are generally comparable, although py-eddy-tracker consistently records more eddy births and deaths in the open ocean than CSS11. Both methods confirm the role of the CI in eddy generation, with births of both signs occurring in the lee of the archipelago. Pearson's r in Table 1 for py-eddy-tracker and CSS11 eddy births and deaths are positive but somewhat smaller than for eddy density, a reflection of the open ocean differences between the methods.

Figure 5 shows comparative maps of mean anticyclonic and cyclonic eddy radius and amplitude. The radius distributions from py-eddy-tracker and CSS11 are

¹ $U/c > 1$, here c is the translational speed of the eddy (CSS11).

FIG. 3. Eddy tracking statistical comparisons for cyclones and anticyclones from py-eddy-tracker and the CSS11 database: (a),(b) eddy lifetimes and respective ratios (CC/AC). The total number of eddies counted are 1965 (py-eddy-tracker) and 1519 (CSS11); (c),(d) eddy radii (L_{spd}) and respective ratios; (e),(f) eddy amplitudes and respective ratios; (g),(h) eddy nonlinearity and respective ratios; (i),(j) comparative scatterplots of eddy radii (L_{spd}) vs amplitude for CC and AC, respectively.

similar, with the largest scales in the open ocean to the south and west (Figs. 5a,b,e,f). However, the CSS11 radii are characteristically larger, as previously seen in Figs. 3c,i,j. Close agreement is evident between the datasets in the distribution and magnitude of mean eddy amplitudes (Figs. 5c,d,g,h).

The good comparative performance between py-eddy-tracker and CSS11 in the CEC analysis domain is

replicated over the SAO and SEP regions, as evidenced by the respective Pearson's r in Table 1.

4. Discussion

The main discrepancies between the CEC py-eddy-tracker results and the eddy track data from CSS11 in section 3 concern L_{spd} eddy radius magnitude and the

FIG. 4. Contour plots of Canary Eddy Corridor mean eddy birth and death counts per 1° square per year from (top) py-eddy-tracker and (bottom) **CSS11**. Anticyclone counts in odd-numbered columns; cyclone counts in even-numbered columns.

offshore distributions of eddy births and deaths. The py-eddy-tracker estimates generally smaller radii and more frequent instances of eddy generation and termination in the open ocean. Similar differences are observed for the SAO and SEP analysis domains.

The py-eddy-tracker eddy identification criteria are arguably stricter than **CSS11**'s owing to the use of a shape test and the limit of a single local minima/maxima within C_{eff} (section 2a). As a result, the probability of identifying large irregularly shaped feature as eddies is greater in the **CSS11** method (cf. the region $L_{\text{spd}} \geq 125$ km, $A \leq 4.5$ cm in Figs. 3i,j). When evaluating such features, py-eddy-tracker iterates farther toward the center before (if symmetry increases and local minima/maxima do not

exceed one) eddies can be identified; those py-eddy-tracker eddies will clearly have smaller L_{eff} than the equivalent **CSS11** eddies, and hence smaller L_{spd} . (Albeit an approximate relationship, **CSS11** report $L_{\text{spd}} \approx 0.7 L_{\text{eff}}$; this value is confirmed for the three analysis domains herein.) A further factor that may influence the L_{spd} bias are the aforementioned inherent differences in SLA treatment (section 2a).

Concerning eddy birth and death densities, we find that in open ocean regions py-eddy-tracker predicts greater frequencies of both events than **CSS11** (Fig. 4; also Fig. 3a). The eddy identification disparity mentioned above may again provide an explanation for the differences: having a stricter eddy identification threshold,

FIG. 5. Contour plots of annual mean Canary Eddy Corridor eddy properties on a $1^\circ \times 1^\circ$ grid from (top) py-eddy-tracker and (bottom) **CSS11**. Anticyclone and cyclone eddy radii (L_{spd}) are shown in the first two columns; the last two columns show anticyclone and cyclone eddy amplitudes.

TABLE 1. Pearson correlation coefficients (r) between anticyclone and cyclone eddy concentrations and eddy polarity (P), as defined in Fig. 2, from py-eddy-tracker and CSS11 for three analysis domains: CEC (18.5°–31.5°N, 35.5°–12.5°W); South Atlantic Ocean (SAO) (49°–16°S, 69°W–29°E); and southeast Pacific (SEP) (30°–10°S, 145°–68°W). Also shown are r for eddy birth and death concentrations (e.g., Fig. 4); $p < 0.01$ for all correlations.

	AC	CC	P	AC _{Births}	CC _{Births}	AC _{Deaths}	CC _{Deaths}
CEC	0.90	0.85	0.61	0.67	0.60	0.56	0.53
SAO	0.88	0.87	0.58	0.59	0.59	0.58	0.59
SEP	0.87	0.87	0.55	0.44	0.48	0.36	0.38

py-eddy-tracker is more likely to terminate a track than CSS11 (hence more deaths); more terminations mean in turn a lower likelihood that genuine new eddies are spuriously linked to existing eddies (hence more births). This delicate balance highlights the important role of the eddy identification procedure. Unfortunately, not having access to CSS11 individual SLA fields, we are unable to directly compare the eddy identification performance of the two algorithms.

5. Concluding remarks

A new oceanic eddy tracking code written in the open source Python language has been introduced. Results from applying the py-eddy-tracker code to SLA data compare favorably with the eddy property database of CSS11. Both methods produce broadly consistent results in terms of eddy locations, scales, and amplitudes within three distinct analysis domains. Discrepancies between the methods relating to eddy scales, and distributions of eddy births and deaths are identified and discussed.

The py-eddy-tracker code works on global SLA over user-defined regions up to basin scale. At global scales the present code slows down significantly. Improving the iteration speed and the addition of oceanic numerical model eddy tracking capability (surface and subsurface) are important next steps.

There is arguably no uniquely correct eddy detection method, but several methods, including that of CSS11 and the code presented herein, produce useful enough results for most purposes of eddy counting. As eddy tracking techniques evolve and data resolution and coverage improve, comprehensive intercomparisons between different oceanic eddy trackers will reveal the extent to which results from the various codes are robust and where there may be large method-related uncertainties (e.g., Souza et al. 2011; Neu et al. 2013).
